THE TREATMENT OF PNEUMONIA IN ST. FRANCIS HOSPITAL.

WITH RESULTS IN TWO HUNDRED AND TWENTY-EIGHT CASES.

BY ARNOT SPENCE, M.D.,

NEW YORK.

IN view of the great mortality of pneumonia, its treatment is a question of pre-eminent importance. It is still, we must admit, in an unsettled state, and for that reason every effort should be made to advance it. In this article the subject of treatment alone will claim attention.

Professor William Osler, in a very interesting paper on "Mortality in Pneumonia," quotes the rate obtained in the Pennsylvania General Hospital, during 1885, 1886, and 1887, as 36.1 per cent. ; and of all the cases since 1845, it was 29.1 per cent. Also, at the Boston City Hospital he says they report a death-rate of 29.1 per cent., when all the cases for the past thirteen years are considered. In the New Orleans Charity Hospital, in a series of nearly four thousand cases, he quotes them as reporting a rate of mortality of 28.01 per cent.

In a report made by Dr. Latta, of 257 cases of pneumonia treated for the Pennsylvania Railroad Relief Department, he gives the death-rate as 20.23 per cent. In explanation of this rather low rate, he describes his patients as strong and healthy men, of temperate habits, and engaged in healthy out door work. Thus he shows his appreciation of the fact that he had the best possible material for good results.

Professor A. L. Loomis reports the mortality as obtained by him, in 255 cases treated in his wards at Bellevue Hospital during a period of four years, as 34.1 per cent. In physical condition his patients were the opposite of those of the Pennsylvania Railroad Relief Department, for nearly one-half of them were complicated cases. These figures suffice to show the great severity of pneumonia, in this country at least ; and they are a sufficient argument in themselves for the presentation of facts in support of a treatment which has given better results.

The cases forming the subject-matter of this report, were treated on the service of Dr. J. H. Ripley, at St. Francis Hospital, during the period from October 1, 1884, to October 1, 1892. As the previous condition and surroundings of the patients are of such importance when comparing the results obtained by different methods of treatment, a few words bearing on these cases cannot fail to be of interest.

They were, with but few exceptions, residents of the East Side tenements, and of most every nationality. The majority, however, were Germans. Owing to the unsanitary state of these dwellings, the hardships of breadwinning, and the dissipations these people indulge in, their physical condition is seldom even fair ; and they are thus heavily handicapped in the struggle with any grave disease. In addition, they allow ignorance and superstition to stand in the way of their well-being, and very often delay applying for treatment until treatment can be of little avail. They are firm believers in the self-limitation of disease, and suffer patiently in the hope that the next day will find them better.

The treatment, as pursued in all of the cases, was in accordance with a plan suggested by Dr. Ripley, and through his directions carried out. To begin with, the bowels were freely moved. For that purpose five grains of calomel, well rubbed up with sugar and milk, was given if the patient's condition allowed ; or if too weak, a more gentle laxative was employed. After the bowels had acted, the following mixture was given, a half ounce every two hours :

℞. Tr. aconiti..... ℥ xxiv.
Tr. opii camphoratæ..... ʒ ij.
Liq. ammonii acetatis,
Syr. zingiberis,..... .....āā ℥ ss.
Aquæ ....q. s. ad ℥ vj.
M. Sig. : ℥ ss. every two hours.

The aconite was given primarily for its effect on the heart and blood-vessels, and thus on the inflamed lung, and secondarily to reduce the temperature. It produces a quieting and slowing of the irritable and rapid heart, and a reduction of the arterial pressure, thereby lessening the amount of blood in the congested lung. It controls the temperature within a safe range, and prevents the marked exacerbations so common in typical cases of this disease. In strong and full-blooded patients, veratrum viride was substituted for the aconite in this mixture, and used in about the same dose. The paregoric is added to ease the short and harassing cough, which is often such a disturber of rest. The spirit of mindererus acts as a diaphoretic, keeping the skin moist, and in its way relieving the kidneys to some extent. Besides assisting thus to keep the temperature down, it is also a stimulant.

Throughout the administration of this mixture the heart was most carefully watched to note the effects of the drugs, and, all things being favorable, it was continued until the fall in temperature denoted the crisis of the disease. When further stimulation seemed necessary, whiskey was freely given, but never unless it was indicated. The administration of alcoholic stimulants all through this disease, as is frequently done, is a practice capable of doing great harm.

In obstinate sleeplessness from any cause, as well as that caused by troublesome cough or pleuritic pain, a drachm of the U. S. solution of morphine was occasionally given at night. The free or constant use of morphine was never resorted to, for its injurious effects in most instances far over-balance any relief it might afford the patient. It masks the signs, which to the observant attendant are the danger signals of the disease, and adds, when given too freely, another and greater danger, by its action in diminishing the number of the respirations, thereby interfering with the proper oxygenation of the blood.

If, notwithstanding the use of this, our pneumonia mixture, the temperature should rise and remain above 104° F., the cold half pack was resorted to in most cases. The antipyretic drugs were given only on rare occasions, and then never by order of the visiting physician, who has always strenuously opposed their use ; but rather in response to the uncontrollable impulse, that seems to be epidemic not alone among the younger members of the profession, that every rise in temperature, whether extreme or otherwise, must be combated by the administration of one of these dangerous drugs. It is unreasonable to expect that a few hours' remission of fever, the result of any of these depressing antipyretics, can better the condition of the patient, or even compensate for the bad effect the drug leaves on the heart. The indiscriminate employment of these antipyretic drugs in every case of fever or rise of temperature, cannot be too severely condemned.

The only attempt at local measures or applications was

the wearing of an oil-silk jacket over the chest, immediately next the skin. This was worn throughout the treatment. While flax-seed poultices, when correctly applied, seem to favorably influence the course of pneumonia in children, they cannot be used with comfort in the adult. For without being of immense bulk and weight, we cannot make them sufficiently large to completely encircle an adult chest; and certainly they are of no value when otherwise applied. The small poultice, equal in size to one's hand, as usually applied by the amateur nurse, is but a useless substitute.

The diet in all of our cases was limited, until convalescence set in, to milk, meat broths, soups, and farinaceous gruels. The reclining posture was preferred, and the patient was not allowed to leave the bed for any purpose. Much praise is due to the nurses, the Sisters in charge of the hospital, for their intelligent and untiring attention to these patients.

During the period mentioned, from October 1, 1884, to October 1, 1892, Dr. Ripley's wards cared for 276 cases of pneumonia; while 228 of those received this particular treatment. These 228 cases can be classified as follows:

	Cases.	Deaths.	Mortality. Per cent.
Croupous pneumonia, uncomplicated	125	18	14.4
Croupous pneumonia, complicated	76	25	32.8
Catarrhal pneumonia, uncomplicated	25	5	20.0
Catarrhal pneumonia, complicated	2	0	0.0
Total number	228	48	21.05

Thus, of the 228 cases treated according to the plan already described, 48 died, showing a mortality-rate of 21.05 per cent.

A glance at the different groups and at the results given, shows very conclusively that the complications which attend this disease, and the affections it is so commonly associated with, have much to do with its great fatality. Notice the low rate, only fourteen per cent., obtained in the uncomplicated cases of croupous pneumonia, or those cases in which only one lung was involved and no other disease coexisted; while in the complicated cases of the same variety the mortality was 32.8 per cent.—two and one-third times as great. That more than one-third of the croupous pneumonia cases were complicated is another important fact. The death-rate of the uncomplicated cases of the catarrhal form was twenty per cent. This was higher than that of the same class of the croupous variety by nearly one-half. Owing to the small number (only two cases) in the complicated group, we cannot make any comparison between the two classes of the catarrhal form of this disease.

Since we have observed in a general way the serious effect these complications have on the main result, it must prove of greater importance to note which of them are most dangerous. In the following table, the cases have been so arranged as to show the number complicated by the different affections, and the number of each that have ended in death:

Variety and Complications.	Cases.	Deaths.
Double croupous pneumonia	13	7
with pleurisy	2	1
with empyema (pyothorax)	1	..
with pleurisy and pericarditis	2	1
with pericarditis and nephritis	1	..
with nephritis and valvular disease of heart	1	1
with miscarriage at 6½ months	1	..
Croupous pneumonia with pleurisy	20	..
with empyema (pyothorax)	3	1
with pleurisy and pericarditis	1	1
with hemorrhagic pleurisy, nephritis, and phthisis	1	..
with pericarditis and valvular disease of heart	2	..
with pericarditis and phthisis	1	1
with valvular disease of the heart	3	..
with valvular disease of heart and acute rheumatism	1	..
with nephritis	4	2
with nephritis and fatty heart	1	1
with phthisis	4	..
with emphysema	2	2
with acute alcoholism	3	3
with chronic alcoholism	1	1
with malarial cachexia	1	..
with acute tonsillitis	1	..
with perihepatitis	1	..
with hepatic abscess and morphine habit	1	..
with purulent infiltration	1	1
with pulmonary abscess	1	1
with cellulitis of the hand	1	1
with melancholia	1	..
Catarrhal pneumonia with pleurisy	1	..
with phthisis	1	..
Total	78	25

Double pneumonia, alone and with other complications, was present in twenty one cases, and of these ten died. Pleurisy, including serous, hemorrhagic, and purulent effusions, occurred in thirty-one cases, four being fatal; two of these were double pneumonias, one having in addition acute pericarditis. In only one case with empyema did death occur. Acute pericarditis was present in seven cases, and caused death in four of them.

Of the co-existing diseases nephritis was present, alone and with other complications, in 8 cases, and 5 of them died. Valvular disease of the heart was present in 7 cases, of which number, one, also complicated by nephritis, died. Phthisis affected 7 of the cases, and only one of these ended fatally. Of our patients, 3 had very serious complications, which fortunately did not cause death. A nineteen-year-old wife miscarried a six and one-half months' fœtus during the height of the pneumonia. The second one was complicated by hemorrhagic pleurisy, phthisis, and chronic nephritis; and the third, a male nurse with the morphine habit, had, in addition to his pneumonia, a hepatic abscess. Thus we had, all told, 78 cases with complications, 25 of which proved fatal. This makes the death-rate, in complicated cases alone, thirty-two per cent.

In the following list the causes of death have been enumerated, and the sex of these cases given:

Causes of Death.	Male.	Female.	Total.
Croupous pneumonia, uncomplicated	14	4	18
Catarrhal pneumonia, uncomplicated	5	.	5
Double croupous pneumonia	7	..	7
with pleurisy	..	1	1
with pleurisy and pericarditis	..	1	1
with nephritis and valvular disease of heart	1	..	1
Croupous pneumonia with empyema (pyothorax).	1	..	1
with pleurisy and pericarditis	1	..	1
with pericarditis and phthisis	1	..	1
with nephritis	1	1	2
with nephritis and fatty heart	..	1	1
with emphysema	2	..	2
with acute alcoholism	3	..	3
with chronic alcoholism	1	..	1
with purulent infiltration	1	..	1
with pulmonary abscess	1	..	1
with cellulitis of hand	1	..	1
Totals	40	8	48

We have classed the cases as uncomplicated so long as the process was confined to one lung, and no other complication existed.

In only 23, or ten per cent. of all the cases, was death due to uncomplicated pneumonia. Again, but 37 of the fatal cases, or 16.2 per cent., had in addition to the pneumonia such complications as commonly spring from it; as extension of the process to the other lung, pleurisy, serous or purulent, and pericarditis. Of the remaining deaths, three per cent. were due to chronic and incurable diseases of the heart, lungs, and kidneys, and 1.7 per cent. to alcoholism. In 1.3 per cent. was death due to septic infection, there being one case each of purulent infiltration of the lung, pulmonary abscess, and cellulitis of the hand.

The mortality caused by uncomplicated deaths, 10.08 per cent., agrees as to the result, with that obtained in 1,000 cases in the Massachusetts General Hospital, which were reported by C. N. Townsend and A. Coolidge, Jr. They concluded that their death-rate was but a little over

ten per cent., after they had omitted of the fatal cases, those that were necessarily fatal, also the deaths occurring in persons who were delicate, or intemperate, or the subject of some complication. Our rate (10.08 per cent.) represents the results after the omission of only complicated cases. A dissipated subject was not put down as an alcoholic case, unless he showed the immediate effects of alcohol while under observation. Should we eliminate all the delicate or intemperate from among our fatal cases this rate would be very decidedly diminished. Only one-sixth of the fatal cases were females, but as it will be shown later on, that is about the proportion of the sexes when all the cases are considered.

When we note separately each year's work, the results obtained were as follows:

Year.	Number of cases.	Number of deaths.	Rate of mortality.	Number of uncomplicated deaths.	Mortality from uncomplicated deaths, per cent.
Oct. 1, '84, to Oct. 1, '85..	35	8	22.8	4	11.4
Oct. 1, '85, to Oct. 1, '86..	27	2	7.4	1	3.7
Oct. 1, '86, to Oct. 1, '87..	21	2	9.5	2	9.5
Oct. 1, '87, to Oct. 1, '88..	22	9	40.9	3	13.6
Oct. 1, '88, to Oct. 1, '89..	22	4	18.1	1	4.5
Oct. 1, '89, to Oct. 1, '90..	28	6	21.4	4	14.2
Oct. 1, '90, to Oct. 1, '91..	34	6	17.6	4	11.7
Oct. 1, '91, to Oct. 1, '92..	93	11	28.2	4	10.2

The most noticeable feature when comparing the results from year to year is the wide variations shown; and this very fact proves the uselessness of drawing conclusions from the treatment of a small collection of cases. In 1885–86 the rate of mortality was only 7.4 per cent., and when the results of 1885–86 and 1886–87 are combined, we have the very low death-rate of 8.3 per cent. in 48 cases. On the other hand, in 1887–88 our mortality was very high, it being 40.9 per cent. During that year we were unfortunate in the class of cases, for 6 of the 9 deaths were due to complications. As to the results of the other years, the table speaks for itself.

The mortality in every year was not in an equal degree affected by the omission of the complicated fatal cases; but in every instance the rate is greatly reduced when these cases are not included. The 40.9 per cent. mortality can in this way be brought down to 13.6 per cent., and even the 8.3 per cent. rate (1885–86 and 1886–87) can be reduced to 4.08 per cent. It is important to note that only one uncomplicated death occurred in each of the two years 1885–86 and 1888–89.

In order to satisfactorily explain the want of agreement in the results obtained during different years, we should have to take into consideration the general physical condition of the patients, their ages, and the variations which are observed in all acute diseases. As an instance of the influence age had on these results, let us look at the ages of the fatal cases occurring in the year when the mortality was so high. Of the 9 deaths none were under thirty years of age; 3 were between thirty and forty years, 2 between forty and fifty, 2 between fifty and sixty; and 1 each at the sixtieth and seventieth year of age. These ages, as will be demonstrated later on, accounted to some extent for that forty per cent. rate.

In order to show that these results vary much less when the cases are arranged in larger groups, we have in the following table divided the cases in larger series:

	Number of recoveries.	Number of deaths.	Rate of mortality, per cent.	Number of uncomplicated deaths.	Mortality from uncomplicated deaths, per cent.
First 100 cases.....	79	21	21.0	10	10.0
Second 100 cases.....	84	16	16.0	10	10.0
1884–88, 105 cases.	84	21	20.0	10	9.5
1888–92, 123 cases.....	96	27	21.9	13	10.5
Total, 228 cases	180	48	21.05	23	10.05

Here the lowest mortality was in the second series of 100 cases only sixteen per cent. Taking a glance at the other groups, the rates are quite constant, there being a variation of less than two per cent. between the lowest and the highest. In the mortality of uncomplicated deaths this difference in the rates is only one per cent. If the first two groups are combined, we have a series of 200 consecutive cases, with a death-rate of only 18.5 per cent. The result obtained after a consideration of all the cases, 21.05 per cent., compares very favorably with the rates of the other hospitals, as quoted at the beginning of this article.

Age.—The patients ranged in age from five to seventy-eight years, there being one case at each of these limits and both recovered. The seventy-eight-year-old patient was a man with a severe pleuro-pneumonia.

Age.	Cases.	Deaths.	Mortality, per cent.
Under 10 years.....	3	0	0.0
From 10 to 20 years.....	18	0	0.0
From 20 to 30 years.....	88	15	17.0
From 30 to 40 years	60	11	18.3
From 40 to 50 years.....	32	10	31.2
From 50 to 60 years.....	15	6	40.0
From 60 to 70 years.....	9	4	44.4
At 70 years and over.....	3	2	66.6

The small number of cases under ten years of age is explained, when it is understood that St. Francis Hospital does not, as a rule, admit children for treatment. Under twenty years of age there were no deaths, while 21 cases below that age were treated. Nearly one-half our patients were under thirty years old, and over two thirds were less than forty years of age. While the mortality of those between twenty and thirty years old was seventeen per cent., when we consider all the cases under thirty years, 109 in number, the rate is only 13.7 per cent. This very low death-rate is undoubtedly due to the vigorous and sound constitutions of these young subjects. There were 169 cases under forty years of age, of which 26, or 15.3 per cent., died; and 201 cases under fifty years, with 36 deaths, a mortality of 17.8 per cent. These figures can be compared with the mortality reported by Dr. Latta, of the Pennsylvania Railroad Relief Department, which has been previously mentioned. In all probability those railroad men were under forty years of age; but in order to allow for some being older, we can place them for comparison in the class of cases under fifty years of age. It will be remembered Dr. Latta's results gave a mortality of 20.23 per cent.

It is interesting to note how steadily the rate runs up with the age, thus proving the great influence that factor has on the main result. To be sure, the small number of cases at the advanced ages, makes the mortality-rates for those periods less valuable; still, for comparison with each other they are sufficiently reliable. This marked influence that age exerts on the mortality can be easily understood. A constitution generally weakened by age cannot hope to battle against an exhausting disease with the same success as a younger one; and again, the patient with advancing years is more likely to be the subject of some chronic disease, which with the advent of pneumonia will help toward a fatal termination. When we inquire into the two deaths that occurred in patients at the seventieth year, we find both died after seven days of treatment; one had a catarrhal pneumonia uncomplicated except by age, and the other a croupous pneumonia complicated by an old emphysema. In like manner, of the four fatal cases between sixty and seventy years of age, two were uncomplicated, except by years. Of the other two, one had double pneumonia, pleurisy, and pericarditis, and the other chronic nephritis and fatty heart in addition to the pneumonia.

While it is generally conceded that this is one of the most fatal of the acute diseases in old age, according to some observers patients over sixty years of age, recover much more frequently than would be supposed. In these patients the grade of fever is not so high, and the process seems to be much less active.

Sex.—The female sex claimed 37 of our cases, and 191 were males. Death terminated the disease in 8 of the female cases, a mortality of 21.6 per cent.; and 40 of the males died, or 20.9 per cent. These figures tend to corroborate the general conclusions, that pneumonia is more fatal among females, while the disease seems to show a preference for the male sex.

Season.—Most of these cases occurred during the changeable and wet months of the spring of the year, the number being nearly as large as those of the fall and winter combined.

	Cases.	Deaths.	Mortality. Per cent.
Summer	30	8	26.6
Autumn	41	8	19.5
Winter	59	11	18.6
Spring	98	21	21.4

While this disease is usually looked upon as most prevalent and fatal during the spring of the year, in our cases the summer months gave the highest mortality. The heat and humidity, so distressing and exhausting to a person sick and confined to bed, are particularly unbearable when the lungs and heart are disabled. This probably explains the increased mortality during the warm season. While the winter gave the lowest rate, during the spring months we had the largest number of cases, with a mortality of only 21.4 per cent.

Thus it is evident that age, sex, and season, all exercise an influence to a greater or less degree on the result, and these we certainly cannot counteract. The complications which caused death in over eleven per cent. of our cases we cannot expect to prevent by any method of treatment, although it must be acknowledged we can modify their course. There is sufficient room for reduction, when we reflect that ten per cent. of our mortality was in uncomplicated cases. While we were able to show a death-rate of only 7.4 per cent. in 27 cases, and 8.3 per cent. in a series of 48, it is hardly to be expected that such results could be realized in a collection of 200 consecutive cases, especially in hospital practice. At the present time, however, the rate of mortality, 21.05 per cent., which has been obtained in these cases, must be considered good.

The claim that can be made for this plan of treatment is that it is rational, and meets the indications as well as they can be met with our present knowledge, and the means at our command. It certainly does not retard nature, but aims to save the strength and aid the resisting power of the patient, until the disease has run its course. That it is of some assistance, is shown by the results we have obtained; a mortality-rate which certainly compares very favorably with that of other hospital reports.

In conclusion, the writer wishes to express his appreciation of the kindness of Dr. J. H. Ripley, in permitting him to report these cases, and his gratitude for valuable suggestions and advice.

70 West Seventy-first Street.

Treatment of Sciatica.—Any new suggestion as to the treatment of sciatica will be welcomed by those who have been impressed with the intractable nature of some of the cases of this malady. In a recent number of the *American Practitioner and News*, Dr. Charles B. Lawrence gives a short account of his experience with different methods of treatment in sciatica. The most instructive case is that of a man, aged fifty-two, a carpenter, who had suffered from sciatica for seven weeks. He was emaciated and pale, and had been taking morphia to relieve his pain and he was now unwilling to leave it off. There was great tenderness along the whole course of the nerve, the patient was unable to use the leg and was in constant pain. Various methods of treatment were tried, but ineffectually. Finally nitro-glycerine was given in an alcoholic solution of one per cent. strength, commencing with a dose of one minim three times a day, gradually increased up to five minims. Improvement was almost immediate, and in ten days the patient was able to walk to his work. A complete recovery ensued.

ABDOMINAL HYSTERECTOMY WITH CLAMPS—A RAPID AND SAFE METHOD OF REMOVING THE UTERUS.[1]

By EMORY LANPHEAR,* M.D., Ph.D.,

Kansas City, Mo.

Professor of Surgery in the University Medical College, Surgeon to the German Hospital and to All Saints' Hospital, Consulting Surgeon to Good Samaritan Hospital.

In discussing the subject of hysterectomy we are compelled to dismiss Freund's operation (dropping the stump of the amputated uterus into the abdominal cavity) because the death-rate is so alarmingly high. The question, therefore, narrows itself to: Which is preferable—amputation close to the cervix with fixation of the stump in the lower angle of the wound, or total extirpation? My answer is: Unquestionably the latter. Those who, like Price, of Philadelphia, have had such satisfactory results from ventral fixation of the stump, reducing the mortality-rate from an average of about eighteen per cent. in reports from all operations—good, bad, and indifferent—to between three per cent. and four per cent., naturally feel wedded to the method, and do not like to try any other as long as their death rate is so low: yet all admit that it has its disadvantages, and that it is wholly unsurgical in character. To leave a stump that is bound to slough, to possibly allow of septic infection, to permit in some cases the formation of a fistula or ventral hernia, and to do an operation that certainly (in many cases) does not completely restore to health—surely a method including these possibilities is not an ideal one. And I have witnessed everyone of these bad results—some in the practice of the most skilful operators the world has ever known: a huge, purulent collection about the stump with septic fever in the hospital of one; a fistulous tract from the umbilicus to the vagina in another; a tremendous hernia in still another; and other disagreeable symptoms in many others. The patient not infrequently suffers greatly from pain produced by the dragging pedicle in the abdominal scar, and from pressure of the fixed stump upon the distorted pelvic organs. Besides all these, abdominal hysterectomy by extra-peritoneal fixation of the pedicle means a long and tedious convalescence, no patient being able to leave her bed before the end of the sixth to the ninth week; and last of all, even the most skilful operators consume much time in making and satisfactorily fixing the pedicle. I have seen Joseph Price occupy one hour and seventeen minutes in completing a hysterectomy in a case I would not regard as especially difficult. Now, if an operation can be devised to overcome all of these difficulties, without equally strong objections, should it not be adopted? Surely! And I believe that total extirpation does this, for most cases at least, and is destined to supersede every other form of abdominal hysterectomy: especially for the reason that it will, in skilled hands, prove even more safe than operation with extra-peritoneal fixation of the stump—almost as safe as ovariotomy.

Having determined to do a total extirpation, one has three methods from which to select:

1. The operation practised by Péan.
2. The operation originated by Eastman.
3. The operation devised by myself.

The Péan Operation.—The Péan method consists of two distinct operations: First, a supra-pubic hysterectomy with wire on the stump, and second, a vaginal "hysterectomy" for removal of the cervix, stump, and wire. Briefly described the procedure is this: After opening the abdomen the tumor is drawn upward by means of a long curved trocar or corkscrew, and an elastic ligature thrown around the uterus as close as possible to the cervix, and fastened by a pair of forceps. The uterus is then resected as close to the ligature as is safe, the bladder and rectum dissected off, all the little vessels belonging to them being tied or compressed. A metal ligature is then placed below the elastic constrictor, tightened firmly by an assistant and twisted. The stump is now cut down as

[1] Read before the Tri-State Medical Society, at Keokuk, Ia., April 5, 1893.

close to the metallic ligature as is practicable without danger of losing it, and the stump and wire dropped into the pelvis; the abdominal wound is then closed and dressed. Extirpation of the cervix, wire, and stump is then made through the vagina, after the manner of a vaginal hysterectomy—by ligating on each side and cutting away.

This is an excellent operation for the removal of very large fibrous, fibro-cystic, or interstitial uterine tumors, and I have employed it with much satisfaction; but it takes a long time—not less than an hour, even by a rapid operator; so that by reason of serious continuance under an anæsthetic, the long exposure of peritoneum to the air, and the aggravated shock of a tedious operation, the mortality has been a little greater than that of abdominal hysterectomy with fixation of the pedicle.

The Eastman Operation.—Eastman, of Indianapolis, has originated, and practised successfully in a number of cases, a method of total extirpation that should be followed in most cases of removal of the uterus through the abdomen. It has been adopted by such operators as Martin, Bardenhauer, and Guermonprez. I have made the operation a number of times, and have assisted my friend, Dr. H. C. Crowell, of Kansas, in other cases, and I must say I regard it as the ideal method. Tersely given, the method is this:

After the abdomen is opened both ovaries and tubes are ligated and cut away, and the peritoneum divided for two or three inches across the tumor (or uterus) just above the vesico-uterine fold, and correspondingly behind; when this has been done a wire or elastic ligature is thrown around the uterus, at the point of division of the peritoneum, and tightened. The peritoneum is then stripped down in front, the bladder carefully dissected away from the uterus, and an opening made into the vagina; a similar separation of rectum from uterus is made, and the peritoneum slipped back on the broad ligaments so that all ligatures are either below or behind the peritoneum, instead of including it in their grasp. Three sets of ligatures (or more if necessary, which is rare) are then passed on each side, including all the vessels and extending through to the vagina; one end of each ligature is left long, and as soon as tumor and uterus have been cut away these ends are carried out through the vagina; by slight traction on these ends the peritoneal edges are easily brought into apposition, and can be rapidly coapted by a continuous catgut suture, thus entirely shutting off the abdominal cavity from the vagina, and preventing any possibility of adhesion of gut to raw surface. The wound in the belly-wall is closed, the vagina irrigated and packed with gauze, the silk ligatures being allowed to slough out and come away per vagina.

In this method there is practically no hemorrhage, the shock is not so intense as in the Péan operation or ordinary abdominal hysterectomy with a pedicle, the difficulties encountered can readily be met by anyone familiar with complicated operations in the pelvis, the time is not quite so great, and convalescence is much more satisfactory than in the operation usually made.

But we who have removed the uterus many times, have more than once wished for a method by which we could speedily terminate an operation always full of anxiety to the operator, and always too prolonged for the safety of the patient; the high mortality that has prevailed in hysterectomy by the most approved method (that of fixation of pedicle in lower angle of wound) has deterred many from advising the operation in patients greatly weakened from disease, or suffering from cardiac or renal lesions which render prolonged anæsthesia highly dangerous. Pozzi, in his most valuable work on gynecology, condemns hysterectomy in: 1, cases where there is excessive debility; 2, advanced age; 3, where many vascular adhesions exist; 4, complications of cancer of the cervix with tumor of the body—this last, he says, being attended by frightful mortality because relapse is certain.

In the first three of these groups the source of danger lies in the length of time required for complete ablation of the uterus and its appendages. Those who are familiar with hysterectomy have said that if the operation could be so simplified as to be done inside of a half hour and without hemorrhage, the high death-rate might be reduced to about that of ovariotomy, viz., three per cent. to five per cent. in skilled hands. In the last of these groups (cancer of the cervix with tumor of the body) recurrence takes place mainly, I think, from the fact that in the usual operations some infected tissue remains behind. Now, if an operation can be made which overcomes the matter of time in the first cases, and allows such careful inspection as to permit removal of all infected tissue in the last cases, many operations can be made successfully that would otherwise be unjustifiable. It has been my very good fortune to originate such a method, a rapid and safe way of removing the uterus in certain cases where the Eastman operation is not advisable or practicable, and I take pleasure in presenting to you five specimens, representing various forms of uterine tumors, together with a brief description of each. One case died from too late removal of the clamps, otherwise I should have an unbroken record.

The manner in which I came to adopt the method may not prove uninteresting. In the summer of 1890, while removing a fibro-cystic tumor of the uterus at the City Hospital, in Kansas City, my ligature, including the circular artery, slipped off just as I cut away the uterus, and in an instant pelvis and vagina were filled with blood; a sponge was inserted and a clamp pushed up through the vagina; by this was caught the bleeding vessel, but in such a way that the clamp had to be left on for thirty-six hours to prevent return of hemorrhage. Subsequently, in discussing the case with my confrère, Dr. J. F. Binnie, of Kansas City, we agreed that if such an expedient proved satisfactory in cases of emergency it should be equally advantageous in certain cases of selection, and so I have found it. The operation is as follows:

The Lanphear Operation.—*Preparatory Treatment.*—The patient should be admitted to the hospital two days before the operation and put to bed. Two nights before the operation compound licorice powder (or magnesium sulphate) is given to thoroughly evacuate the bowels; this dose is repeated the evening prior to operation, at which time the patient is given a bath and the abdomen and pubes shaved, scrubbed with soap and water, dried, iodoform rubbed freely in, and all covered with a pad of iodoform gauze; if the patient be extremely nervous this preliminary cleansing may be dispensed with, but is better done. On the morning of operation the rectum is thoroughly washed out with a copious enema, with a vaginal douche of hot boric-acid solution. The patient is put under the anæsthetic in her own bed and then removed to the operating-table. The abdomen, pubes, vulva, and inner sides of the thighs are again scrubbed with soap and water, dried, and washed with sulphuric ether. At this point the hands of operator and assistant, previously well scrubbed, are washed with a saturated solution of potassium permanganate until of a deep mahogany color, then decolorized with a strong solution of oxalic acid. The same solutions are then used upon the woman, and final rinsing of hands, abdomen, and vulva made with a solution of bichloride of mercury, 1 to 1,000; the vagina is washed out with the same solution. At this point antiseptics disappear from the operation, hot water being used for irrigation, sponges, etc. No antiseptic can be used in the abdomen—we must have ideal asepsis and not depend on antiseptic solutions.[1] The parts are surrounded by towels wrung out of hot water, each leg

[1] I recently read an account in the *Kansas Medical Catalogue*, of an exploratory laparotomy (for enlarged spleen) where the surgeon irrigated the abdomen with hot bichloride solution and put in a drainage-tube! The reporter of the case naïvely adds: "The patient died a few hours later!" Of course she did; how could it be otherwise? Some men who enjoy considerable prominence do not seem to understand these things. I have had surgeons of considerable experience inquire: Why all this detail in preparing the patient? I answer that no other method than that I have described can be regarded as absolutely safe, and in abdominal surgery no operator can afford to neglect even the slightest point. As much frequently depends upon the preparations and after-treatment as on the operation itself.

and the chest being first wrapped in blankets, and the patient is ready for operation.

Instruments.—The instruments required are knife, two scissors (one curved and blunt-pointed and one straight), two abdominal retractors, one perineal retractor, one large and one small vulsellum, two clamps for the ovaries, two Polk clamps, one blunt herniotomy needle (curved to the left) for carrying the ligatures, two dissecting forceps, hæmostatic forceps, needles, and a *serre nœuds* with wire (or an elastic ligature) to be prepared for either a Péan or Eastman operation, if necessity arise. These instruments must be boiled for five minutes in a solution of carbonate of sodium (common "washing soda," not the bicarbonate) one teaspoonful to the quart of water, and then washed in cold sterilized water and kept immersed in hot water during the operation. If silk be used, it also must be boiled. During the operation neither operator nor assistant must touch anything which has not been sterilized—this is the fundamental rule in my operating-room and cannot too often be repeated, even by experienced operators.

Accessories.—Plenty of catgut must be at hand, large, medium, and small. This must be juniperized—carbolized gut is never to be trusted. The "sponges" should be made of cotton carefully wrapped in iodoform gauze, and at least twenty-four in number. Hot water in basins, and irrigators and cold sterilized water in pitchers, also iodoform and dressings must be close by. Two assistants are useful, but one may do, besides the anæsthetist, and one nurse.

Operation.—An incision is made in the abdominal wall close to the middle line, four inches or more in length; not more than thirty seconds to one minute should be required for opening the belly.[1] As soon as exposed the ovary and tube of one side are caught and pulled into the opening, and a clamp applied to their outer side, as close to the uterine body as possible. A heavy catgut ligature is passed through the broad ligament, enclosing about an inch or more of tissue, tied, and a cut made between the ligature and the clamp; this suturing may be continued downward into the pelvis as far as is convenient. The other side is then treated in the same manner, when the uterus with its attached tubes and ovaries, with the clamps, may be brought up into the opening. Unless this preliminary suturing and dividing is done, much valuable time will be lost in attempting to urge the fundus into view (in small tumors), or to reach the attachment of the bladder to the uterus; because of the extreme tension of the broad ligament only one side of the uterus can be brought into view at one time, and no amount of force can lift it up until the broad ligaments are divided. But as soon as this is done the circular shape of the bladder disappears, the organ extending itself outward and backward, the corrugations of peritoneum upon its border ceasing to be prominent. The fundus is now tilted backward, a cut made transversely across the uterus, through the peritoneum, and separation of bladder from womb made methodically and completely. This line of incision should be made just behind the vesico-uterine fold, which is easily recognized by touch; this dissection is made partly by fingers and partly with blunt-pointed, curved scissors, the bladder being pushed away little by little, below and in front. When the region of the os tincæ is reached a nurse separates the legs of the patient and the operator slips one finger into the vagina, locates the proper point near the os, and pushes the scissors through the mucous membrane; this opening is extended across the anterior surface of the cervix, as in the initial stage of a vaginal hysterectomy, save that the cut is made from above instead of below. The uterus now being pushed strongly forward, a similar separation of the uterus from the rectum is made; but not nearly so much care is required, as the distance is short and perforation of the rectum not so easy. When the cul-de-sac of Douglas is well opened the uterus is given into the hands of an assistant, who pulls it upward and to one side; a Polk clamp (such as is used in vaginal hysterectomy) is inserted through the vagina with one hand, while the other is within the pelvis to guide the blades into place. The clamp is made to hug the uterus closely so as to avoid catching the ureter; its point must come up to the ligature that has already been tied in the broad ligament. (Some difficulty may be experienced in getting the blade which goes through the posterior opening into place, and I am not sure but inexperienced operators would do well to employ a curved clamp rather than the straight clamp of Polk.) When all of the tissues lying at the side of the uterus, from cervix up to the cut in the broad ligament, are found to be within the grasp of the blades, the clamp is closed and the handle given to the nurse; the uterus is carried over to the other side, the fellow-clamp applied in the same manner, and the uterus, tumor, tubes, and ovaries cut away, the scissors cutting as close to the clamps as possible. The mass is extricated through the abdominal opening, the irrigator used from above until all clots and débris are washed out of the vagina. The pelvic cavity is then carefully dried and bladder and rectum allowed to fall together. If it be seen that some raw surface is left exposed in the pelvis the peritoneum of the posterior wall of the bladder may be united to that of the anterior wall of the rectum by a few catgut stitches; but I have thus far found in practice that this step is unnecessary, particularly where extreme haste is required, all raw surfaces being hidden by the bladder falling backward, so that adhesion of intestine is not a possibility. The peritoneum is closed by a continuous catgut suture, and the wound sewed with either interrupted catgut stitches or silk worm-gut—the former by preference. The usual dressings of iodoform, bichloride gauze, cotton, and surgeon's plaster are then applied, the vagina gently sponged and loosely packed with iodoform gauze, and the clamps tied and surrounded as in cases of vaginal hysterectomy.

As thus performed, supra-vaginal hysterectomy is scarcely more serious than vaginal, the cut through the abdominal wall adding but an insignificant amount of danger to the operation. In cases where the tumor is too large to admit of this procedure the elastic ligature may be applied, amputation done, then the cuts into the vagina made in the manner described and the clamps applied. In cases of cancer of the neck complicated with tumor of the body (as will be seen by examination of the specimens), I have heretofore made the operation described, but I believe it will be better surgery to do the Péan operation in such cases, removal of the cancerous tissue per vagina containing no possibility of infection by mere contact, as might be the case if it touched peritoneum.

If there are reasons why the minimum time of exposure of peritoneum should be secured, a preliminary step may be made, namely: the cuts may be made before and behind the cervix through the vagina, as in vaginal hysterectomy; when completed nearly to the peritoneum, the abdomen may be opened above and the further steps carried out.

Cases.—Specimen 1 is a sarcoma of the body of the uterus taken from a patient thirty-six years of age, never pregnant, with very close pelvis. The woman presented the usual symptoms of a uterine tumor—repeated and exhausting hemorrhages, expulsive pains, headaches, etc. For weeks before admission to hospital she had been in bed, and was *in extremis* when brought to the city. The uterus was found eight inches in depth, nearly as wide, bleeding readily, and closely bound down by adhesions from an old pelvic peritonitis. She had suffered for years from mitral regurgitation of severe grade. In spite of this grave condition, I made hysterectomy by this method; occupied a comparatively short time in operating, and sent patient home in excellent shape four and a half weeks afterward.

Specimen 2 is an œdematous myoma which weighed

[1] I have seen, more than once, fifteen to twenty minutes of valuable time lost in entering the abdomen—this is inexcusable—chronic surgery.

eighteen pounds when fresh. The history was one of long-continued hemorrhages, beginning at the age of forty four and persisting until the forty-eighth year, with general ill-health. The patient was in desperately bad condition, but the operation passed without any accident or bad feature. A wire was put around the cervix below the growth and tightened, the uterus opened, and the tumor "shelled out" in spite of the great area of attachments as shown in the specimen, and then the operation completed in the usual way. Owing to the necessity for opening the womb and separation of tumor from the uterine walls, fifty minutes were consumed in the operation.

Specimen 3 is one of multiple fibroma removed from a patient aged thirty-five, who was in excellent health, and had no complaint save that of rapid growth of a nodular tumor of the abdomen. The only peculiar thing about this case was the ease and rapidity of operating. There were no adhesions, the tumor was easily accessible as soon as the ovaries and tubes were cut loose. No inflammatory deposits being present, separation was easily accomplished, and the operation was completed in twenty-seven minutes.

Specimen 4 is a fibro-cystic tumor of the uterus, complicated by cancer of the neck. The cysts were very large, one containing several pints of fluid, and the fibrous part too large to be extracted through a narrow pelvis. The cancerous mass was therefore curetted away, and the vagina rendered as nearly pure as possible, and the operation made from above, with clamps from below. Little difficulty was experienced in completing the whole operation in a little more than forty minutes.

The clamps were left on somewhat more than forty-eight hours, and in removal tore away some of the tissues undergoing pressure necrosis: secondary hemorrhage at once carried the patient to the great beyond. I am sure, if the clamps had been taken away in about thirty hours —before the tissues became so softened—this accident would not have occurred. If hemorrhage is to be arrested at all by clamps, twenty-four hours will see all danger passed, and the forceps should be removed.

Specimen 5 is a myoma of considerable size, associated with epithelioma of the cervix. As will be seen, the tubes and ovaries are still attached (as in the other specimens also), and microscopic examination shows cancerous tissue in the tubes, thus emphasizing the point made a few paragraphs back: cancer of the cervix means that the ovaries and tubes should be removed whenever operation for radical cure is made.

Conclusions.—1. Total extirpation is always preferable to supra-pubic hysterectomy with ventral fixation of the stump.

2. In cases of large tumors the Eastman operation is the ideal method of hysterectomy.

3. When cancer of the neck is complicated with large tumor of the uterus, the Péan operation should be preferred.

4. Whenever there is special reason for extreme haste the Lanphear operation gives the best prospect for recovery.

5. The advantages of the latter method are: (*a*) It is the most rapid method yet devised for supra-pubic removal of the uterus; (*b*) it leaves no pedicle to become necrotic and give rise to septic infection or develop a fistula; (*c*) there is not so much danger of hemorrhage as after ovariotomy, and no more than in the Péan method; (*d*) it is not nearly so complicated as many other abdominal and pelvic operations; (*e*) it is the safest method of total extirpation, at least in the hands of those not wholly familiar with tying ligatures deep in the pelvis; (*f*) it affords more rapid convalescence than does any other form of hysterectomy.

Glycerin for a Cough.—In severe paroxysms of coughing from whatever cause, a tablespoonful of glycerin in hot milk or cream will give speedy relief.—*Annals of Hygiene.*

THE OPERATIVE TREATMENT OF HERNIA IN CHILDREN, WITH A REPORT OF FIFTY-ONE CASES.

By WILLIAM B. COLEY, M.D.,

ASSISTANT SURGEON TO HERNIA DEPARTMENT OF THE HOSPITAL FOR RUPTURED AND CRIPPLED; SURGEON TO THE NEW YORK CANCER HOSPITAL.

During the past two years 2,174 new cases of hernia, occurring in children under the age of fourteen years, were treated at the Hospital for Ruptured and Crippled. In addition to these cases, a much larger number, recorded in preceding years, yet returning for further observation and treatment, were seen. As the great majority of these cases were treated by mechanical means, and hence have but an indirect bearing upon the subject of this paper, they will be referred to only in the briefest way.

In looking back over the various operations devised for the cure of hernia during the last decade, we are struck with two main facts which go far toward explaining the present attitude of many of the profession in regard to operative procedures. This attitude may be characterized as one of doubt, or at least of very limited faith, and the two facts that have been referred to as explaining it are, first, the too indiscriminate application of imperfect methods; second, the tendency to expect uniformly perfect and lasting results, and falling short of these, to consider all such operations failures. There is really no reason why the operation for the cure or relief of hernia should be judged by a standard entirely different from that adopted in deciding the merits or defects of other operations. Few, if any, are so successful that failures do not sometimes occur, and it seems to me that operations for the cure of hernia should stand or fall according as they fulfil these two conditions of all operations (except emergency): First, a mortality either *nil*, or not greater than that associated with the condition prior to operation. Second, a reasonable hope of success, either in the shape of cure or of relief. Furthermore, there is a tendency to estimate the value of the operation from the results of the older and less perfect methods, without recognizing the great advances made during the past four years.

Time will not permit me to review or criticise the various methods that have been, and still are, employed to cure hernia by operation, and even if it did, the object of this paper would be better accomplished by confining myself chiefly to personal and clinical observations.

I shall assume that the majority of physicians and surgeons admit, under certain conditions, the advisability of operating upon hernia in adults, however they may differ as to the extent and limitations of such conditions.

The question of applying the same operative procedures to children cannot be disposed of so easily, for the reason that up to very recently we have had insufficient data for the drawing of any conclusions of value.

Indications and Contra-indications for Operation.—The indications for operation may be classed as follows:

1. Cases of adherent omentum.
2. Cases complicated with reducible hydrocele.
3. Cases irreducible and strangulated.
4. Cases unable to obtain the care and attention requisite for successful mechanical treatment.
5. Cases where mechanical treatment has been faithfully tried for a number of years without benefit.

These five classes seem to me to embrace all hernia in children to which operative measures should be extended. It now remains to look at these indications more closely, and then we shall examine the contra-indications in the light of clinical experience, in order that we may judge how far they obtain.

Adherent Omentum.—This condition, though much less frequent in children, is occasionally met with, and when present interferes materially with mechanical treatment.

Reducible Hydrocele Associated with Hernia.—This is not a very rare complication, and after repeated and persistent attempts to treat such cases by means of a truss, I am convinced that operation is the only proper method of treatment.

Irreducible and Strangulated Hernia.—In strangulated hernia nearly all will admit the advisability of operation, after taxis, under anæsthesia, has failed to give relief. The operation, if done early, is not dangerous, while the delay necessary to the carrying out of any other method of treatment is not infrequently responsible for the fatal results.

Among the poorer classes seen at a dispensary clinic there are a number of cases without parents or anyone sufficiently interested or intelligent to give the necessary attention to a truss; and these cases I believe to be proper subjects for operation, mechanical treatment having been thoroughly tried.

The supposed contra-indications are: 1. The general belief that all cases of hernia in children can be cured without operation, a belief that is not supported by facts, as shown by a careful analysis of 600 cases under the age of ten years treated at the Hospital for Ruptured and Crippled. 2. The belief that strangulated hernia almost never occurs in children, and hence the condition is not dangerous. Strangulation, though infrequent, does occur, four cases having been seen at the hospital during the past year. The third and chief objection is that operation is attended with greater risk in children, and that the final results are less satisfactory.

Karewski, of Berlin, has recently collected and tabulated 81 cases of operation for hernia in children under five years of age. Of these, 74 were reducible and 7 strangulated. There were 5 deaths, of which 4 occurred in strangulated cases, and the fifth was the result of shock from prolonged operation, in a child two years of age. The mortality, then, in the 74 non-strangulated cases was 1.3 per cent.

As to wound-healing and final results, we find that 39 cases were well and free from relapse one year and longer after operation, while 7 relapses were noted. Suppuration occurred in thirty-three per cent. of the cases; yet when we consider the number of different operators represented, together with the fact that the operations date back for a period of ten years or more, the wound-healing is seen to be quite as good as in adult cases under similar conditions. In fact, the results are better than those obtained in Billroth's Klinik—136 cases, reported by Haidenhain [1] in 1890—in which suppuration occurred in fifty per cent. and relapse in thirty per cent. To these 81 cases collected by Karewski I have added 169 new cases where operation has been performed under the age of fourteen, making a total of 250.

Of these 250 cases—

	Cases.	Relapses.	Deaths.
Bassini operated upon	36	1	0
Poor (of New York)	24	1	0
Bayer	11	0	0
Manley	7	1	0
Karewski (own cases)	9	0	0
Karewski (collected cases exclusive of Bassini's)	50	6	1
Championnière	18	0	0
Halstead	28	2	0
Bull, W. T.	21	8	1
Coley	46	2	0
	250	21	2

Thus we find in 250 non-strangulated cases but two deaths, or a mortality of $\frac{8}{10}$ of one per cent., or less than the lowest mortality of any adult statistics. But nineteen relapses, or 8.6 per cent., were observed. The two deaths that occurred were both in cases under two years of age, and both were irreducible and complicated with extensive adhesions, necessitating a prolonged operation.

Personal Observations.—During the past fifteen months at the Hospital for Ruptured and Crippled I have operated upon 46 cases of hernia in children, 42 of which were non-strangulated and between the ages of four and fourteen years. The 4 strangulated cases were aged eight weeks, eight months, seven and one-half months and one year, respectively. There has been no mortality in the non-strangulated cases although many were difficult and complicated, and but a single death in the strangulated cases, that of a baby eight weeks old. The hernia was of the cæcal variety, and there had been acute strangulation with constant vomiting for upward of twelve hours, and the infant was practically in collapse when first seen. It revived after the operation and lived three days.

Wound Healing.—Absolute primary union occurred in 44 of the 46 cases, and the suppuration in the 2 remaining was due to the use of silk instead of animal suture. Nearly all of the cases were up and about the wards at the end of two and a half weeks. The eight months' baby that was operated upon for strangulation left the hospital at the end of one week, union by first intention having occurred.

Method of Operation.—The Czerny-Risel method was employed in a few of the earlier cases, but the great majority, thirty-two in number, were operated upon by the Bassini method, kangaroo tendon being used for the buried sutures. This method has given by far the most satisfactory results, and when once familiar with its technique it is not difficult to perform.

Upon the choice of suture material, next to the choice of method, depends, I believe, the success or failure of the operation. Silk is regarded by many as the best kind of suture, but the majority of surgeons, in spite of every precaution, have been unable to bury it in the hernial canal without causing subsequent trouble. In Billroth's 136 cases (Czerny method) silk was used instead of catgut, and in 77 cases followed up 38, or fifty per cent., suppurated. It was repeatedly tried at the New York Hospital with the same results, and in the only 2 cases of suppuration which occurred in my 46 cases, the result was due to the silk suture. I do not deny that it can be used without producing sinuses and interfering with primary wound-healing in some cases, but I believe that the danger is a real one, and that since we have other and better suture material, silk should be discarded in hernia operations.

The kangaroo tendon, or the ox-peritoneum, fulfils all the requirements for a buried suture in the hernial operation. They have no tendency to produce slow-healing sinuses, as is the case with silk, and to a less degree with silkworm-gut, and yet they remain unabsorbed for a period of three months or more, as shown by the recent experiments of Ballance and Edmunds,[1] a period sufficiently long to insure a thorough agglutination of the parts.

It has been claimed by the followers of Macewen and others that it is immaterial whether or not the suture is absorbed after ten days or two weeks, since sufficient union will have taken place at the end of that time. Clinical experience will not bear out this statement. Macewen's own brilliant results cannot be taken as evidence, since he used not only catgut of a large size but chromicized in addition, so that it probably remained unabsorbed for one or two months. Directly bearing on this point may be cited the recent experiments of Busse [2] on the suture of tendons in animals. His experiments prove that union of tendons seldom if ever occurs within ten weeks. The successful closure of the inguinal canal depends chiefly upon the more or less firm union secured between Poupart's ligament—a tendinous structure—on the one hand, and the tissues of the internal oblique muscle and conjoined tendon on the other. There is no evidence to show that such union occurs in the short space of ten days. On the contrary, there is much to prove that it does not.

Three years ago, at the Hospital for Ruptured and Crippled, sixteen children were operated upon with catgut sutures; six recurred within the first year, most of them shortly after the operation. I cannot but think that buried kangaroo sutures secure better approximation of several layers, and therefore a more permanent closure than the so-called "crossed suture" advocated by Dr. G. R. Fowler, that has to be withdrawn at the end of five or six weeks. Another advantage is that the period of

[1] Ballance and Edmunds: Ligature of Arteries in Continuity, 1892.
[2] O. Busse: Deutsche Zeit. f. Chir., 1891–92, 31.

required for the healing of the wound, is shortened from three to four weeks, an important consideration with most patients.

Wound Treatment.—No drainage has been employed in any of my cases, and I believe it to be unnecessary.

In addition to the regular antiseptic dressings of iodoform and bichloride gauze, a plaster-of-Paris casing extending from the umbilicus to the foot is applied, and to this fact is undoubtedly due, in a large measure, the uniform success in obtaining primary healing. The dressing is left undisturbed for eight days, at the end of which time the plaster is removed and only an ordinary muslin spica applied.

As fine catgut is used in closing the skin portion of the wound, the dressing does not have to be changed earlier to remove the stitches.

Final Results.—The cases have all been operated upon during the past eighteen months, it is therefore too early to estimate the number of permanent cures. All the cases have been kept under observation, and most of them recently seen. Two relapses have occurred, one following a Czerny operation, the other a Bassini. Both failures were early cases, and due to faulty technique and the use of silk suture, which caused suppuration. Both occurred within three months after operation. A Bassini operation was performed upon the case of relapse from the Czerny method, and the patient was recently seen, perfectly sound, one year later.

The Bassini method was adopted because no other method has given such brilliant and permanent results. Bassini's own cases, 251 in number, all but 4 of which were traced, showed but 7 relapses and no mortality; 108 were free from recurrence from one to four and a half years afterward, while 47 had passed the two-year limit.[1]

The results of Championnière, Macewen, and Kocher, although exceedingly good, are inferior to Bassini's. Whatever method is adopted, I believe prompt primary wound-healing essential to success, and that all variations in technique that interfere with such healing should be abandoned. In proof of this, most of Halstead's 6 relapses (in 58 cases) failed to heal primarily, and the same is true of nearly all of Kocher's recurrences.

In addition to the 32 cases in children, I have operated upon 16 adults by the Bassini method. Of these 48 cases, but one relapse, already referred to, has taken place, and I obtained perfect primary union in 46 successive cases.

Limitations as to Age.—I believe that few cases other than strangulation require an operation under the age of four years. There are few under that age that cannot be controlled by a truss.

My 46 cases have been arranged in tabular form, and I shall not give them in detail. Several of them, however, are of sufficient importance to deserve special notice.

In 6 cases the hernia was of cæcal variety.

Two were the strangulated. Three occurred in children, aged four years, and one in a child of ten. All were very large, and it was absolutely impossible to control them with a truss. One case was complicated with spinal disease and incontinence of urine, yet primary union was obtained. In another, a long appendix was found adherent to the sac, almost to its tip. In one strangulated case the hernia was removed. In three cases adherent omentum, and in four reducible hydrocele of the sac existed.

A form of hernia rarely found in children, viz., femoral, occurred in two cases, one in a boy, aged seven. He had an old inguinal hernia on the opposite side. Both were operated upon the same day. In the femoral the sac was ligated high up and the opening closed with a purse-string suture of kangaroo tendon. The boy was up and about at the end of two and a half weeks. The case of strangulated hernia in the child, one year old, was of exceptional interest. The condition at the time of operation was very bad. The Bassini operation was quickly done under chloroform anæsthesia. The child reacted well, but the temperature steadily rose, and the following morning recorded 107° F., with a pulse of 150 to 160, and respiration 40 to 50. The abdomen was distended and tender, and the child was apparently nearly moribund. It was treated with half-hour tub-baths at a temperature of 100° F., cooled down to 95° F., and repeated when the temperature rose above 104° F., or about every two or three hours, for two days. After two days the child began to improve, and recovery was interrupted. In spite of the unfavorable conditions the wound healed by absolute primary union.

Operations for Hernia in Children, by W. B. Coley.

No.	Diagnosis.	Sex.	Age.	Nature of hernia, and history.	Duration.	Truss.	Date of operation.	Operation.	Operator.	Results.
1	Incarcerated omental with effusion.	M.	8 yrs.	Right inguinal; size, egg.	Congenital.	Yes.	Dec. 12, 1891.	Czerny operation. Hydrocele of cord in addition to hernial sac; small bit of incarcerated omentum; no drainage.	W. B. Coley.	Primary union, 3 weeks; no recurrence, 6 months.
2	Large oblique inguinal hernia; reducible.	M.	13 yrs.	Size, orange; right; not held by truss.	3 years.	Yes.	Dec. 28, 1891.	Bassini operation. Silk suture; no drainage.	"	Suppuration; silk ligature came away, 5 weeks; recurrence, 5 weeks.
3	Reducible; ioguinal oblique.	M.	6 yrs.	Egg; portion not reducible.	2 years.	Yes.	Jan., 1892....	Czerny. Hydrocele of cord sac found alongside of true hernial sac; no drainage.	"	Primary union; no relapse, 1 year.
4	Reducible; inguinal oblique.	M.	8 yrs.	Small egg; not held with truss; left.	Congenital.	Yes.	Jan., 1892....	Czerny. Hydrocele of cord sac with true hernial sac; drainage.	W. T. Bull.	Slight suppuration; no recurrence, 1 year.
5	Inguinal; reducible; oblique.,	M.	9 yrs.	Small egg; not held; right.	4 years.	Yes.	Jan., 1892....	Czerny. No drainage; silk sutures.	W. B. Coley.	Primary union; sinus soon formed, and silk sutures; came away, 3 months; truss could not be worn, and slight recurrence, 3 months; Bassini's operation; well, 1 year later.
6	Inguinal; reducible; oblique.	M.	13 yrs.	Egg; not held.....	11 yrs.; probably congenital.	Yes.	Jan., 1892....	Czerny. No drainage; chromicized catgut for canal; old congenital sac and new acquired sac found.	"	Primary union; no recurrence, 1 year.
7	Inguinal; reducible; oblique.	M.	10 yrs.	Small egg; left; not held.	Congenital.	Yes.	Feb., 1892....	Czerny. Small sac of old hydrocele of cord; chromic acid catgut; no drainage.	"	Primary union; no relapse, 1 year.
8	Irreducible; adherent omental.	M.	7 yrs.	Small egg; not held...	3 years.	Yes.	March, 1892..	Bassini. Large mass of adherent omentum removed; chromicized catgut; no drainage.	"	Primary union; sound, 1 year.
9 10	Very large double inguinal; reducible.	M.	7½ yrs.	Left, orange; right, egg; not held.	4 years.	Yes.	April, 1892...	Czerny. Both sides; one operation; no drainage; chromicized catgut.	"	Primary union; sound, 11 months.
11 12	Left inguinal, right femoral.	M.	7 yrs.	Inguinal: cured by truss; recurred; egg; femoral; 6 mos.; not held; almond.	3 years.	Yes.	April, 1892...	Bassini. Operation for inguinal; purse-string suture to crural canal in femoral; kangaroo tendon suture.*	"	Primary union, both sides, 3½ weeks; sound, 1 month.

[1] The kangaroo tendon in all cases was obtained from Dr. H. O. Marcy, of Boston, to whom great credit is due for bringing to notice the merits of this suture material.

[1] A recent personal communication shows that Bassini has operated upon 560 cases, with no mortality and but 15 relapses.

Operations for Hernia in Children.—Continued.

No.	Diagnosis.	Sex.	Age.	Nature of hernia, and history.	Duration.	Truss.	Date of operation.	Operation.	Operator.	Results.
13	Large inguinal; reducible; oblique.	M.	13 yrs.	Wore truss several years; not held: goose egg.	11 years.	Yes.	May 5, 1892..	Bassini operation. Very large sac, admitting two fingers; small bit of adherent omentum at neck of sac; kangaroo tendon suture.	W. B. Coley.	Primary union; sound, 10 months.
14	Large inguinal; irreducible; adherent omental.	M.	7½ yrs.	Right; small egg.....	Several years.	No.	June 6, 1892..	Bassini operation. Kangaroo tendon; sac adherent to testis; tunica vaginalis opened; sutured with catgut; sac removed; omentum excised.	"	Primary union; sound, 1 year.
15	Inguinal; reducible.	M.	4½ yrs.	Truss; not effective...	2 years.	Yes.	June 14, 1892.	Bassini operation. Kangaroo tendon.	"	Primary union; well, 1 year.
16	Right inguinal; relapsed case (No. 5 of Czerny operation).	M.	4 yrs.	Truss; painful..	3 mos.	Yes.	June 21, 1892.	Bassini. Tendon suture.....	"	Primary union; perfectly firm 1 year after.
17	Right inguinal; strangulated.	M.	8 mos.	Strangulated	Congenital.	Yes.	July 8, 1892..	Czerny. Catgut suture... ..	"	Primary union; well 9 months after.
18	Right inguinal... ...	M.	10 yrs.	Reducible		Yes.	July, 1892....	Bassini. Kangaroo tendon..	Charles W. Wilson, House Surgeon.	Primary union; sound, 9 months.
19	Left inguinal..	M.	14 yrs.	Goose egg.....	Congenital	Yes.	July, 26, 1892.	Bassini. Kangaroo tendon; portion of sac left and sutured over testis.	W. B. Coley.	Primary union; sound, 9 months.
20	Right inguinal.....	M.	10 yrs.	Reducible; size, fist...	Congenital.	Yes.	July, 26, 1892.	Bassini. Complicated with reducible hydrocele; half pint fluid withdrawn from sac and abdomen.	"	Primary union; sound, 9 months.
21	Left oblique..	M.	14 yrs.	Reducible; egg.....	1½ year.	Yes.	Aug. 23, 1892..	Bassini. Kangaroo tendon..	"	Primary union; sound, 7 months.
22	Left oblique.....	M.	12 yrs.	Reducible	6 years.	Yes.	Aug., 1892...	Bassini. Kangaroo tendon..	"	Primary union; sound, 7 months.
23	Large cæcal	M.	4 yrs.	Reducible; uncontrollable.	Congenital.	Yes.	Sept. 13, 1892.	Sac sutured and deep kangaroo tendon suture to canal as in Bassini; cord not changed.	"	Primary union; sound, 6 months.
24	Right oblique.....	M.	11 yrs.	Reducible		Yes.	Sept., 1892...	Bassini. Kangaroo.....	"	Primary union; sound, 6 months.
25	Right oblique.....	M.	6 yrs.	Reducible; hydrocele; complicated.	Congenital.	Yes.	Oct., 1892....	Bassini. Kangaroo tendon..	"	Primary union; sound, 5 months.
26	Right oblique inguinal	M.	14 yrs.	Egg; congenital; cured by truss; relapsed 6 months ago.	Congenital.	Yes.	Oct. 29, 1892..	Bassini. Kangaroo tendon; no drainage.	"	Primary union; well, 4 months.
27	Left oblique inguinal.	M.	12 yrs.	Orange; ring admitted two fingers.	Congenital.	Yes.	Nov. 1, 1892..	Bassini. Suture of sac; kangaroo tendon; omentum very troublesome; no drainage.	"	Primary union; sound, 4 months.
28	Right oblique.....	M.	4 yrs.	Small hen's egg; not held by truss.	Congenital.	Yes.	Nov. 4, 1892..	Bassini. Kangaroo tendon: lower portion of sac sutured over testis; no drainage.	"	Primary union: well, 4 months.
29	Right oblique.....	M.	11 yrs.	Egg; not held by truss.	Congenital.	Yes.	Nov. 29, 1892.	Bassini. Kangaroo tendon; no drainage.	"	Primary union; sound, 4 months.
30	Right cæcal.....	M.	4 yrs.	Orange; not controlled with truss; complicated; spinal disease and incontinence of urine.	2 years; acquired.	Yes.	Dec. 26, 1892.	Bassini. Kangaroo tendon; no drainage.	"	Primary union; sound, 3 months.
31	Right oblique.....	M.	8 yrs.	Complicated with undescended testis.	Congenital.	Yes.	Jan. 13, 1893.	Bassini. Kangaroo tendon; testis anchored in scrotum; no drainage.	"	Primary union; sound, 3 months.
32	Right oblique.....	M.	6 yrs.	Size of hen's egg; complicated with reducible hydrocele.	Several years.	Yes.	Jan. 20, 1893.	Bassini. Kangaroo tendon; no drainage.	"	Primary union; sound, 2 months.
33	Left oblique.....	M.	9 yrs.	Size of hen's egg.....	4 years.	Yes.	Jan. 24, 1893.	Bassini. Kangaroo tendon; no drainage.	"	Primary union; sound, 2 months.
34	Left oblique.	M.	14 yrs.	Size of hen's egg.....	2 years.	Yes.	Jan. 27, 1893.	Bassini. Kangaroo tendon; no drainage.	"	Primary union; sound, 2 months.
35	Left oblique.....	M.	7 yrs.	Size of hen's egg.....	2 years.	Yes.	Feb., 1893 ...	Bassini. Kangaroo tendon; no drainage.	"	Primary union; sound, 2 months.
36	Left oblique; strangulated; 24 hours.	M.	1 year.	Size of goose egg.....	Few months.	No.	Feb. 24, 1893.	Bassini. Kangaroo tendon; no drainage; temperature 99° F. next day; cold baths treatment; recovery.	"	Primary union; left hospital end of 1 week; sound at present, June, 1893.
37	Right oblique with undescended testis.	M.	13 yrs.	Size of hen's egg.....	Congenital.	Yes.	Feb. 28, 1893.	Bassini. Kangaroo tendon no drainage.	"	Primary union; sound, April, 1893.
38	Right oblique with undescended testis.	M.	15 yrs.	Size, egg.....	Congenital.	Yes.	March 3, 1893.	Bassini. Kangaroo tendon; no drainage; testis and epididymis separated; testis anchored in scrotum; wire frame.	"	Primary union.
39	Right oblique.....	F.	10 yrs.	Size of hen's egg.....	Congenital.	Yes; 10 years.	March 6, 1893.	Bassini's operation as far as possible in female; kangaroo tendon; no drainage.	"	Primary union.
40	Right oblique, cæcal.	M.	10 yrs.	Size, goose egg	Since 3 months old.	Yes; 10 years.	March 24, '93.	Bassini. Kangaroo tendon; no drainage; appendix in sac and firmly adherent; adhesions separated and sac sutured.	"	Primary union.
41	Right oblique; inguinal.	M.	5 yrs.	Hen's egg.....	Since a few months old.	Yes.	March 31, '93.	Bassini. Kangaroo tendon..	"	Primary union.
42	Right femoral; incarcerated.	F.	14 yrs.	English walnut..	3 years.	No.	April 4, 1893..	Purse string suture of canal, kangaroo tendon.	"	Primary union.
43	Double inguinal...	M.	13 yrs.	Egg; double recurrence from Czerny operation, 1890.	2½ yrs.	Yes.	April 11, 1893.	Bassini. Both sides; kangaroo tendon.	"	Primary union.
44	}									
45	Right inguinal	M.	6 yrs.	Egg.....	3 yrs.	Yes.	April 18, 1893.	Bassini	"	Primary union.
46	Cæcal and appendix strangulated twenty four hours.	M.	7½ mos.	Egg.....	Congenital.	Yes.	May 18, 1893	Bassini. Appendix removed.	"	Primary union.
47	Right femoral.....	M.	11 yrs.	Walnut.....	4 yrs.	Yes.	May, 1893.	Ligature sac; purse-string suture of canal. Bassini.	"	Primary union.
48	Cæcal	M.	4½ yrs.	Goose egg.....	Congenital.	Yes.	June 16, 1893.	Bassini.	"	Primary union.
49	Cæcal and appendix strangulated	M.	8 weeks.	Large hen's egg.....	Congenital.	No.	June 16, 1892.	Child nearly moribund at time of operation; peritonitis already present.	"	Died on third day.
50	Right inguinal... ..	M.	9 yrs.	Egg.....	Congenital.	Yes.	June 23, 1893.	Bassini. Kangaroo tendon..	"	....

In three cases the hernia was complicated with undescended testis. The testis was brought down and anchored in the scrotum. A wire frame was made use of in two cases, and in a third the epididymis was dissected from the testis, thus increasing the length by nearly one inch. The result was very satisfactory as regards the hernia, but in two cases the testis retracted to the external ring.

The question of what is the best method of dealing with the undescended testis complicating hernia is still *sub judice*. There is some ground for believing that the majority of them are functionally of no value, and therefore one is warranted in removing them. We know that this is generally true as regards domestic animals, especially the horse, and Mr. Owens, of Glasgow, has demonstrated the same to be true in several cases in man. Championnière in his 275 cases of hernia, operated upon 10 with undescended testis. In 5 he removed the organ, and in 5 he anchored it in the scrotum by Tuffier's method.

My object in presenting these cases has not been an attempt to prove the advisability of operating upon hernia in children in general, for I believe that most cases can be cured without operation, but rather an effort to show that there are certain cases in children that cannot be cured by mechanical means, and that the operation is practically devoid of risk, while at the same time it gives results superior to those in adults.

It should be remembered that these 46 cases operated upon have been selected from upward of 4,000 cases of hernia in children, and hence represent less than one per cent. of the entire number treated.

18 East Thirty-second Street.

A NEW INSTRUMENT FOR CONTROLLING TONSILLAR HEMORRHAGE.[1]

By H. HOYLE BUTTS, M.D.,

Instructor of Rhinology and Laryngology, New York Post-Graduate Medical School and Hospital; Assistant Surgeon to the Manhattan Eye and Ear Hospital, Throat Department, New York.

The instrument which I present to the Section this evening is one designed to be of service to the surgeon in controlling alarming or persistent hemorrhage after tonsillotomy. Although the necessity for such a device is comparatively infrequent, yet, when it exists, it is extremely urgent. That there are occasions, after amputation or incision of one or both tonsils, when some sure method of controlling bleeding is demanded, is evident from the appended list of fifty reported cases in which the hemorrhage was sufficiently profuse to endanger life. Three of these cases terminated fatally.

It is useless for me to discuss here the various safe methods of operation on the tonsils, with which you have become familiar through the writings of Morell Mackenzie, Lefferts, Delavan, Knight, Moure, and others. Sufficient to say, that in this enlightened age, with the perfected tonsillotome and the different applications of the galvano-cautery to this purpose, either for igni puncture or with the loop, as utilized by Knight in his electric tonsil snare, it is indeed unfortunate if the surgeon, with this wide field to choose from, meets with uncontrollable hemorrhage. However, such accidents may and do happen to the most experienced operators, through no negligence on their part. If the subject for operation fails to disclose that he is a hæmophile, and inspection and palpation do not discover to the surgeon that there exist vascular anomalies, other conditions being favorable, it is justifiable to consider the case as one adapted to a cutting operation. In connection with these remarks, it may not be uncalled for to mention and emphasize one condition of the tonsil that sensible operators have learned to approach with respect, and as a rule exclude from their cutting procedures, namely, the small, white, and indurated gland frequently seen in the adult pharynx.

In looking over the literature concerning tonsillar hemorrhage, it will be observed that the whole gamut of styptics has been traversed, and very rarely, if ever, have any of these drugs proven of service, unless combined with pressure. The much-vaunted combination of tannic and gallic acids, three parts of the former to one of the latter, as suggested by Mackenzie, may be of some use to control capillary bleeding that would probably cease spontaneously in a few minutes if left alone. Certainly it could not be expected to seal the mouth of a spurting artery of any considerable size, that is surrounded and held open by dense fibrous tissue. As a rule, then, it may be said that these drugs are inadequate to the emergency for which they have been recommended. If the hemorrhage is really of a serious and dangerous character, then some surgical or mechanical interference becomes imperative to prevent exsanguination, unless by a happy chance the patient goes into a condition of syncope, when the bleeding ceases as the arterial tension is lowered. In some few cases of serious hemorrhage, where the artery is exposed, simple torsion with the forceps is all that is required. Oftentimes, though, the walls of the vessel will be found brittle or cannot be seized, and it will then be necessary to transfix the stump of the tonsil, if enough of it remain, with a needle, and surround the mass with a silver-wire ligature. These two methods, with the use of the actual or galvano-cautery applied to the bleeding points, practically include all minor surgical aids. It has been quite thoroughly demonstrated that the ligation of either the common or internal carotid arteries singly cannot be relied upon, so that the only hope in this direction is to tie both of these vessels, or the external carotid near its origin from the common carotid artery. The idea of tying one of the great vessels of the neck is apt to appear rather formidable to many, and justly so, if the same result may be attained by other means.

As to what constitutes an "alarming" hemorrhage arising from the tonsils, no general precept can be laid down; each individual case must be judged in itself, therefore the amount can only be defined as relative. It may be stated, in a general way, that after the excision of a tonsil in a child, it is customary to expect bleeding, varying in quantity from one drachm to two ounces. If the amount more nearly approaches the maximum degree mentioned, it is usually quite brisk for two or three minutes, and then subsides altogether. If the operation has been conducted under the primary effects of a general anæsthetic, a certain proportion of the amount of blood already designated is apt to find its way into the stomach and be vomited later; this may excite apprehension on the part of the patient or his family, who fear that it indicates a return of the bleeding. They should therefore be warned of the probability of this event.

The vast majority of subjects presented for operation are children under fourteen years of age, and have been sufferers from tonsillar hypertrophy for a year or more. For this reason they are likely to have an anæmic appearance, pasty complexions, open mouths, dull, expressionless eyes, and undeveloped physiques. To the group just described every drachm of blood needlessly lost at the time of operation means a delay in their restoration to good health. To the others of more robust constitution the loss of a little more blood is of no great moment, as nature speedily repairs the deficit. Every precaution should be taken to guard against secondary hemorrhage, and this may best be accomplished by operating at the patient's home, so that he may be put to bed at once. Whoever is left in charge of the patient should be instructed to see that he is kept perfectly quiet for the succeeding twenty-four or forty-eight hours, and not permitted to use the voice more than is absolutely demanded. Profound sleep after deep ether narcosis should not be allowed for several hours, as there have been reported several instances of serious results, due to a return of hemor-

[1] Read before the Section in Laryngology and Rhinology of the New York Academy of Medicine, April 26, 1893.

rhage which remained undetected. Only cold, soft food will be found acceptable to the patient, and is all that should be given. Small pieces of broken ice, held in the mouth, will be grateful to the patient's lacerated throat, and tend to prevent a recurrence of the bleeding. After several days have elapsed, a mild antiseptic spray or gargle will be found of service. These simple preventive measures, conscientiously fulfilled, will render the chances of a secondary hemorrhage infinitely small and insure peace of mind to all parties concerned.

The general consensus of opinion on the subject of checking tonsillar hemorrhage convinces one that the simplest and most successful method has been that of direct pressure to the bleeding surface. So far the mechanical aids to this procedure have been found faulty in contrivance, or impracticable for actual use, and the surgeon has been obliged to resort to nature's only provision for this unexpected event, to wit, the use of his fingers. It matters not whether the bleeding occurs from a large, spurting artery that has been severed in one tonsil, or is in the character of prolonged, excessive oozing from both sides of the fauces, he will be forced to introduce one or two fingers, of one or both hands into the mouth, as the case may be, and keep up pressure with them until the result is accomplished. In a few cases with which the writer is familiar, this pressure has been required for several hours continuously; not a pleasant task, even when the operator is helped and relieved by competent assistants. At best, digital compression must be limited, uneven, and unsatisfactory, as the hands become tired. I am in hopes that we have here an efficient substitute for this exhausting and indifferent mode of checking tonsillar hemorrhage. The instrument is readily placed in position, and its effect may be noted, when it is *in situ*, by the use of the head-mirror, which is rather a difficult task when the patient's oro-pharynx is occupied by the surgeon's fingers.

Description of the Instrument.—It is six and three-

quarter inches in length and consists of two parallel steel blades, locked together at the point where they join their handles. To the tips of the blades, which are four inches long and are curved outward and backward in their last half inch, there are attached on the outside, and at right angles, ovoid pads, through which the compression is exerted. The pads are of metal and are symmetrical; each one is an inch long and half an inch wide at its base from which it gradually tapers to the apex, where it measures one-eighth of an inch in width. The surface of the pad is directed outward and backward, is convex in shape, perfectly smooth, and has rounded edges. The handles of the instrument are bent downward, and are continuous with the shafts; they are connected at their extremities by a threaded screw rod that passes through and emerges from the right one; at the outer side of the latter there is a milled wheel that travels on this rod, serving to hold the pressure at any given place. A spring of moderate strength has been inserted between the handles to create enough resistance to the pressure of the hand to insure a firm grip on the instrument when it is in use, and to close it when at rest. By the approximation of the handles the pressure-pads may be separated to four inches, a limit which will be found to be more than ample for the purpose intended.

In shape the instrument has been as closely as possible adapted to the conformation of the mouth. The curve at the extremity allows it to clear the base of the tongue, thereby preventing useless irritation and discomfort to the patient, with consequent gagging. The only parts of the instrument that come in contact with the mouth or pharynx are the pads, with which the direct pressure is made. If desired, the pressure of the instrument may be supplemented by the hands of an assistant placed on the outer side of the subject's neck, support being thus given to the tissues against which the force is being exerted. If deemed necessary, the pressure-pads may be wound with a styptic cotton, to hasten the formation of blood-clots in the injured vessels. The instrument is readily taken apart and cleansed, and may, therefore, be rendered perfectly aseptic.

In order to derive satisfaction from the use of the instrument the manipulation should be as follows: Having placed the patient in the best obtainable light, and his mouth being widely opened, the tongue should be depressed with a spatula held in the operator's right hand, and the tip of the instrument, directed by the movements of the left hand, quickly introduced and carried back into the pharynx, so that the pressure-pads will be at a point slightly beyond the bleeding surfaces; the distal end should then be opened widely enough to cause firm pressure with the pads upon the area of wounded tissue. This is done by closing the spring handles with the grasp of the left hand. The tongue depressor may now be discarded, leaving the right hand free to work the wheel running on the thread of the connecting-rod. By virtue of this wheel, which works rapidly, the amount of compression exerted on the bleeding parts may be nicely adjusted, and increased or diminished at will. Whenever it is wished to greatly augment the pressure, it should be accomplished by means of the handles and not by turning the wheel; the latter is primarily designed to hold the degree of force applied at a fixed point, as determined by the surgeon, thus it is made constant and even. These details having been properly carried out by the operator, and the practically unlimited power at his command considered, makes the question of his ability to arrest hemorrhage from the tonsils a less doubtful one than formerly.

Naturally, the first thought that arises in one's mind in considering a device of this kind, and intended for use in the sensitive region of the oro-pharynx, is whether it can be tolerated by the subject on whom it is designed to be employed? My experience with the instrument convinces me that it can be borne in any throat, providing the operator is possessed of a moderate degree of skill and manual dexterity. It has been tested by application to the tonsillar regions of many subjects, varying in age from ten to fifty years. Usually the adult subject, with which we have mostly to deal, has some control over the faucial and palatal muscles, and, as general anæsthetics are rarely given for a tonsillotomy after the age of puberty has been attained, the co-operation of the patient may be relied upon to some extent, as affecting posture and the exercising of enough will-power to prevent gagging. The muscular contractions caused by the presence of the instrument are less than those produced by the fingers when employed for the same purpose, and with delicate management may be so far overcome that pressure on the cut vessels will be endured long enough to allow them to become closed by blood coagula. Should the patient lose all control of himself, fearing that he is about to die, and persuasion failing, force should be used in subduing him in order to prevent such a catastrophe. In the event of such an occurrence, a mouth-gag would be of service to insure the instrument being retained in position.

An analysis of these forty-six reported cases of alarming tonsillar hemorrhage shows that only four of them were under fifteen years of age, and five others are mentioned as being "young," presumably young adults.

That the use of ether is advisable, to induce a condition of general anæsthesia in a very young subject for tonsillotomy, is generally conceded by those who have had an extensive practice in this branch of surgery; besides causing the absence of pain, it has the advantage of

placing the subject under the entire control of the operator, and in case of excessive bleeding renders the use of such an instrument as this one comparatively easy.

The instrument is placed before you with the hope that, in using it, the surgeon will be spared many moments of anxious suspense after operation on the tonsils.

The tonsillar hæmostat was made for me by C. E. Riker, surgical-instrument maker, of this city.

Forty-six Cases of Alarming Tonsillar Hemorrhage.[1]

Sex.	Age.	Disease.	Instrument used.	Result.	Operator, reporter, and remarks.
Male.....	21	Hypertrophy of tonsils.	.....	Recovery.	Gayat: Thèse, Paris, 1868, No. 275, p. 52. Jarjavay operated; right tonsil removed.
Male.....	35	.....	.....	Recovery.	Broca: Paris, operator, 1869. Both tonsils removed: patient a hæmophile; hemorrhage stopped in two hours by direct application of ice.
Female...	20	.....	.....	Recovery.	Ditto: Operator. No details.
Male.....	.....	Hypertrophy of left tonsil.	Bistoury.	Recovery.	Dr. Wharton F. Hood: *Lancet*, 1870, vol. ii., p. 600. Small calculus within tonsil; vomiting stopped hemorrhage.
Male.....	.....	.....	.....	Recovery.	Ditto: No details; both tonsils excised; sulphate of zinc administered; vomiting, hemorrhage stopped.
Male.....	31	Syphilitic enlargement of right tonsil.	Hook and bistoury.	Recovery.	Dr. Güntner: Oestern. Zeitschr. f. prakt. Heilk., Wien, 1872, xviii., No. 52, p. 839. Patient a hæmophile; syphilitic; common carotid ligated.
Male.....	Young.	Hypertrophy of tonsils.	Amygdalatome.	Recovery.	Mary: Thèse, Paris, 1875, No. 29. Operatioo by patient himself. Hemorrhage stopped with perchloride of iron.
.....	.....	.....	.....	Recovery.	Agnew's System of Surgery, vol. ii., p. 991. McCarthy, London Hospital, ligated common carotid artery for hemorrhage after tonsillotomy.
.....	.....	.....	Probably bistoury.	Recovery.	Ditto: Velpeau reported four cases of dangerous hemorrhage from injury to the internal carotid.
Female...	Middle.	Hypertrophy of right tonsil.	Amygdalatome.	Recovery.	Dr. A. M. Fauntleroy, Amer. Med. Weekly, Louisville, ii., 1875, p. 498. Patient was very full-blooded; ice-packing upon neck employed.
Male.....	18	Hypertrophy of tonsil.	Guillotine.	Recovery.	Dr. L. D. Kastenbine: Louisville Med. News, i., 1876, pp. 280, 281. Hemorrhage stopped by patient walking home with mouth open.
Male.....	24–25	.....	.....	Fatal.	Broca: Paris, operator, 1879. No details.
Male.....	8½	Double tonsillar angina; hypertrophy.	Amygdalatome.	Fatal.	Ditto: Nov., 1879. Cause of hemorrhage, anomalous internal carotid artery.
Male.....	20	.....	.....	Recovery.	Dr. Saint Germain: No details; hemorrhage stopped by ice applied around the throat.
Female...	.....	Hypertrophy of tonsils.	Forceps and blunt bistoury.	Recovery.	Dr. Cidon: 1880, Hygeia, Stockholm, xlii., 1881, p. 256. Ligation of common carotid.
Male.....	25	Hypertrophy of tonsil.	Tonsil bistoury.	Recovery.	Dr. G. M. Lefferts: Arch. of Laryngol., New York, iii., 1882, p. 37. Pressure applied directly on surface.
Male.....	35	Hypertrophy of tonsil.	Mackenzie's amygdalatome.	Recovery.	Ditto: Hemorrhage from artery at right stump; artery twisted, hemorrhage stopped.
Female...	Young.	.....	Amygdalatome.	Recovery.	Ditto: Artery twisted.
Male.....	.....	Hypertrophy of right tonsil.	Amygdalatome.	Recovery.	Ditto: Ditto:
Male.....	46	Hypertrophied tonsils.	Mackenzie's amygdalatome.	Recovery.	Felix Semon: Rep. St. Thomas's Hospital, 1882, p. 85. Hemorrhage from both tonsils; ice, gargles of alum, tannic acid and perchloride of iron failed to stop bleeding. Controlled by digital pressure.
Female...	23	Hypertrophied tonsils.	Mackenzie's amygdalatome.	Recovery.	Ditto: Rep. St. Thomas's Hospital, 1883, vol. xiii., p. 129. Persistent oozing from both tonsils; styptics and digital pressure failed; patient put to bed and the bleeding stopped in three hours.
Female...	30	Enlargement of left tonsil, acute inflammation.	Mackenzie's amygdalatome.	Recovery.	Dr. Clinton Wagner: Tr. of the Am. Laryngolog. Assoc., 1886, New York, 1887, viii., p. 185. Artery twisted with forceps.
Male.....	Young.	.....	.....	Recovery.	Ricordeau: Thèse, Paris, 1886; Reclus, operator. Both tonsils removed.
Male.....	34	Ch. follicular amygdalitis.	Mackenzie's for right toosil, and tonsil-sickle for left tonsil.	Recovery.	Dr. J. Walker Downie: Edinb. M. J., xxxii., 1886–87, p. 116. Hemorrhage stopped by actual cautery.
Male.....	Young.	Hypertrophy of tonsil.	.....	Recovery.	Dr. Briddon: Med. News, Phila., May 28, 1887. Hemorrhage from small spurting vessel for three days; injected persulphate of iron, which controlled bleeding.
Male.....	31	.....	Cautery.	Recovery.	Dr. Werner: Oct. 11, 1887. Med. Cor. Bl. d. Würtemb. ärztl. Ver., Stutt., lviii., 1888, p. 241. Manual compression of carotids for ten days.
Female...	18	Hypertrophy of tonsil.	Amygdalatome.	Recovery.	Christopher Lewis: Brit. Med. Jour., Sept. 15, 1888. Large vessel behind anterior pillar severed; torsion failed; combined external and internal pressure with finger controlled bleeding.
Male.....	21	Hypertrophy of tonsil.	Amygdalatome.	Recovery.	Ditto: Profuse hemorrhage came on five hours after operation. Pressure with perchloride of iron swab controlled the bleeding.
Female...	Middle.	Hypertrophy of tonsil.	Amygdalatome.	Recovery.	Ditto: Hemorrhage came on two hours after operation. Firm and continuous pressure with perchloride swab stopped the bleeding.
Female...	Adult.	Acute inflammation of tonsil.	Bistoury.	Fatal.	Reported by Dr. H. C. Murphy: Albany Med. Annals, 1888, ix., p. 18. Fatal hemorrhage resulting from puncture of tonsil with knife.
Male.....	25	Hypertrophy of tonsil.	Mathieu's amygdalatome.	Recovery.	Dr. S. E. Fuller: Amer. Jour. of the Med. Sci., Phila., xcv., 1888, p. 357. Common carotid ligated; saline solution (12 oz.) transfused into radial vein.
Male.....	21	Quinsy.	Mathieu's amygdalatome.	Recovery.	Dr. L. E. Blair: Albany Med. Ann., ix., 1888, pp. 41–47. Hemorrhage from left tonsil; ice and compression.
Male.....	27	Acute tonsillitis.	Mathieu's amygdalatome.	Recovery.	Ditto: Hemorrhage from right tonsil; stopped by compression.
Male.....	22	Hypertrophy of tonsils.	Volsella and scissors.	Recovery.	Dr. E. W. Clarke reported and performed ligation: Dr. T. M. Markoe, operator, N. Y. M. J., xlviii., 1888, p. 7. Hemorrhage stopped by ligation of the stump.
Male.....	Young.	.....	Amygdalatome.	Recovery.	Dr. Daly: Tr. of the Am. Laryngolog. Assoc., 1888, N. Y., 1889. Hemorrhage stopped by compression.
Male.....	34	.....	Amygdalatome.	Recovery.	Dr. D. Bryson Delavan: Tr. Am. Laryngolog. Assoc., x., 1888, N. Y., 1889, pp. 153–165.
Female...	7	.....	Fahnestock's.	Recovery.	Ditto: Patient was a hæmophile.
Male.....	Adult.	.....	Guillotine.	Recovery.	Dr. R. J. Lewis: Med. News, Phila., liii., 1888, p. 640. Hemorrhage stopped by application of a tenaculum through base of tonsil, and twisting it.
Male.....	.....	.....	.....	Recovery.	Dr. A. Vander Veer, reporter; Dr. Alden March, operator: Albany Med. Annals, ix., 1888, pp. 41–47. No details given.
Male.....	48	Hypertrophy of tonsils.	Mathieu's amygdalatome.	Recovery.	Dr. F. Park Lewis: J. of Ophth., Otol., and Laryngol., N. Y., i., 1889, pp. 115–117. Hemorrhage four quarts in seventeen hours from left tonsil.
Female..	14	Hypertrophy of tonsil.	Mathieu's amygdalatome.	Recovery.	Dr. J. S. Butler: N. Y. Med. Rec., Nov. 2, 1889. Hemorrhage from right tonsil; ice, tannu-gallic acid, and pressure failed; stump was surrounded by silver-wire ligature, and left in position for two days.
Male.....	Adult.	Acute tonsillitis.	Amygdalatome.	Recovery.	Maure: Société de Chirurgie, April 20, 1890. Severe hemorrhage from left side on the night following operation; controlled with difficulty by iced drinks and pressure. A similar bleeding occurred eight hours later without apparent cause.
Female...	Adult.	Acute tonsillitis.	Amygdalatome.	Recovery.	Dr. W. E. Greene: Jour. Ophth., O., and Laryngol., N. Y., 1891; iii., p. 138. Hemorrhage five hours after operation; continuous pressure for one-half hour controlled it.
Female...	Adult.	Hypertrophied tonsils.	.....	Recovery.	Ditto: Bleeding began in both stumps one hour after operation; controlled by cauterization.
Male.....	3½	Peri-tonsillar abscess.	.....	Recovery.	Dr. T. C. Dunn: Univ. Med. Mag., May, 1891. Hemorrhage following peri-tonsillar abscess; ligation of the common carotid.
.....	.....	.....	.....	Recovery.	M. M. Krasin: Drevnik obsh. vrach. pri imp Kazan Univ., 1892; iii., pp. 110–123. Two cases of hemorrhage threatening life after tonsillotomy.

313 Madison Avenue.

[1] Thirty-one cases reported in the above table appeared in an article by Dr. Jonathan Wright, New York Medical Journal, August 30, 1890, p. 235.

Clinical Department.

PUERPERAL FEVER AND ERYSIPELAS.

Infant One Month Old with Erysipelas of Head, Face, Neck, Trunk, and Extremities—Recovery.

By DILLON J. SPATSWOOD, M.D.,

FAIRFORD, ALA.

As the almost universal verdict of the medical profession is that puerperal fever is caused by septic absorption, I thought it would be of some interest to the readers of the Medical Record to relate the history of the following case, which undoubtedly makes it appear that the zymotic diseases play some part in the etiology of puerperal fever, the reverse of which is true in this case.

I was called to see Mr. R——'s child, aged one month, on April 10th, at 10 A.M. There was a small red spot just below the external ear; temperature, 101° F. An antipyretic was prescribed, and the neck ordered to be powdered with the following: Zinci oxidi, ʒ iv.; starch, ℥ j.

The same afternoon I was called again hurriedly, as the child had had a slight convulsion. I found the temperature 105⅖° F. The redness had extended from the external ear over the entire side of the head and neck, and to the middle of the face, and had involved the external palpebral portion of the left eye. The redness was of a deep crimson, with the characteristic glaze and œdema of erysipelas. All medicine administered was rejected by the stomach, but the bowels were regular and nourishment was retained.

Second day.—Temperature, 103° F. in the morning; 104⅜° F. in afternoon. Œdema and redness continue.

Third day.—Temperature, 102° F. in morning; 104° F. in afternoon. The redness and œdema are beginning to disappear on the left side of the face, and coming on almost exactly in the same place on the other side of the head; extending around, involving the face and scalp exactly in the manner as the left side had been affected.

The temperature ranged for the next seven days from 101° to 103½° F. The redness and œdema were disappearing on the tenth day from both sides of the face and head. The temperature was normal on the eleventh day, and to all appearance the child had recovered.

Upon the twelfth day redness and œdema returned on both sides of the face and head, this time involving the occiput, and entire posterior cervical portion of the body. The temperature again rose to 104° F., and continued for three days, never going below 102° F., although an antipyretic was administered.

Upon the third day of the relapse red spots were discovered upon every portion of the trunk and extremities, upon the fourth began to fade on the face and head, and upon the fifth disappeared entirely from the face and head. But upon the feet and body the redness and œdema were very marked, causing the child to scream with pain when handled. Now, when the phenomena of the disease were at their height upon the body and extremities, the eruption appeared for the third time on the cheeks and scalp, and remained for two days. During the relapse the fever never reached the height it did during the first illness. Upon the eleventh day after the relapse the child's temperature was normal, and it was nursing and sleeping well.

The mother of the infant had been taken with puerperal fever four days after delivery. A midwife had attended the case during labor, and of course no antiseptic precautions had been taken. But as soon as I was called the case was treated antiseptically with bichloride, vaginal injections, etc. Now the question arises from whence did this new-born infant get the erysipelas? I had no cases under treatment, and there had been none in the neighborhood for the past two months. Many instances are cited in text-books where puerperal fever is contracted from erysipelas—Can the reverse be true?

As this case was extremely severe, and the infant only one month old, I will briefly give the treatment which proved successful. As the stomach rejected all medicine the following was given per rectum: Quin. sulph, gr. ij.; syr. ferri chloridi, ʒ ss., in emulsion of acacia, with a wine-glass of warm water, every four hours. When the temperature went above 102° F., antipyrine, gr. j., sodii bromidi, gr. iv.; liq. ammon. act., ʒ ss., in orange syrup, was administered, with excellent result, every three hours until the fever fell below 101° F.

Bichloride 1 to 2,000 solution was used to sponge all over the head and neck and around the edges of the inflammation. The affected portion was kept freely anointed with an ointment of aristol, ʒ j., in vaseline, ℥ j.

When the eruption spread all over the body, bichloride baths of 1 to 5,000 (warm) were given, and the aristol ointment was freely used afterward. During the relapse remedies were administered by the stomach. Amorphous syr. of quin., ʒ j., three times daily. Syr. ferri chloridi, pepsin cordial, āā ʒ ss., after nursing, four times a day. Immediately upon the appearance of the disease the infant was taken from the mother's breast and put upon Horlick's malted milk, which agreed with it excellently.

It gives me pleasure to state that the child has entirely recovered, and though the treatment may seem heroic for an infant of one month, I may safely remind my critics that "there is no success like success." This is not a case where the patient was cured, but died of something else.

POST-PARTUM APPENDICITIS.

By H. M. NEALE, M.D.,

UPPER LEHIGH, PA.

During the past few years several cases of appendicular inflammation in women, which developed immediately after childbirth, have come under my observation. And so frequently have I noticed this condition that I am now thoroughly convinced that there is some cause for this phenomenon other than the extension of an inflammation of either septic or traumatic origin from the organs more directly concerned in the act of parturition. Having then arrived at the conclusion that this disease is more common in women who have recently passed through an accouchement than at other times, the next thing is to endeavor to account for it satisfactorily. The most reasonable explanation for the occurrence of appendicitis at this particular time, that suggests itself to my mind, is the fact that the cæcum is filled, or partially filled, as the case may be, with fecal matter during the process of labor. When the pains become harder and harder, and the intervals between the pains become shorter and shorter, and the contractions of the abdominal muscles are violent, the contents of the abdominal cavity are subjected to a high degree of pressure; this may force the contents of the cæcum, or a portion of them, into the appendix, and an inflammation of a more or less serious character may result. The degree of inflammation resulting from this accident will be influenced by the nature of the substance which finds its way into the appendix. If only a fluid or semi-solid substance enters the appendix, the resulting inflammation will probably be slight, owing to the fact that as the appendix swells and an exudation is thrown out, and as the walls of the appendix begin to distend, the contents will partially or entirely pass back again into the cæcum and the inflammation rapidly subside. When an appendicitis of the nature just described is present we may have scarcely any constitutional symptoms, or they may be very severe, and subject to the same changes and influences that characterize inflammation elsewhere. I have seen many cases where the patient has complained, a few days after confinement, of pains in the right iliac region, with tenderness on palpation, with constipation usually, but not always, present; and in some instances the usual symptoms of inflammation of the appendix were present, such as slight chills, fever, vomiting, etc., while in other cases the constitutional symptoms have been practically nil. In most ot

the cases of this character a tumor could be felt at McBurney's point which was very painful to the touch but disappeared quickly after the acute symptoms began to subside. When symptoms like these present themselves, I infer that an appendicitis due to ingesta being forced into the appendix has supervened, and as these cases usually recover without serious results, it is reasonable to suppose that the cause of the trouble is due to a comparatively non-irritating substance, and has been removed in the manner described. On the other hand, two cases have recently come under my observation of an appendicitis of a very serious nature following labor, in which operation verified the correctness of the diagnosis. In the more serious cases it is safe to suppose that either a solid substance, such as a grape-seed or a lemon-seed or some foreign body not easily gotten rid of, has found its way into the appendix, or that there has been a rapid extension of the inflammation due to a weak and debilitated condition of the patients, which would render them peculiarly susceptible to the inflammatory process. Having observed these conditions for several years I have come to the conclusion that many of the so-called cases of "pelvic abscess," "pelvic cellulitis," "inflammation of the ovary," "salpingitis," etc., that follow childbirth are in reality appendicitis caused in the manner just described. I can now recall three cases of relapsing appendicitis that date the beginning of this trouble from confinement; one case has recently come under my care in which the patient has complained of pains in the right side since her last confinement, nine years ago; she is very thin, and a small mass, irregular in shape, can be easily felt about the cæcum, and seems to conform to the convolutions of the colon, giving rise to the suspicion that the walls of the colon are thickened and indurated. In view of these facts I am satisfied that this condition is much more common than is usually supposed.

Progress of Medical Science.

Sudden Death in a Case of Abscess of the Liver.—At a meeting of the Orleans Parish (La.) Medical Society, Dr. A. J. Bloch reported a case of abscess of the liver that had come under his care. Prior to January, 1892, the patient had experienced good health, but at that time had an attack of fever with pain in the right side which confined him to bed. Treatment was of little benefit, and the nature of the case was not quite evident until, in a fit of coughing, he expectorated a quantity of liver pus. Exploration revealed the presence of a cavity in the right lobe of the liver. On April 1, 1893, Dr. Bloch resected the rib and made a large opening into the abscess cavity, removing fully one pint of very foul pus. Fearing to irrigate under chloroform, as the cavity communicated with the lung, he packed the cavity with iodoform gauze. The patient rallied well; his pulse, as before the operation, was 155 a minute; his respirations 40. The following day the cavity was irrigated with a two per cent. solution of carbolic acid and a drainage-tube was substituted for the gauze. The change in his condition the next week was phenomenal; his temperature became normal; his pulse was reduced to 110, stronger and fuller; his appetite was inordinate; his respirations from 24 to 28 a minute. Each day the cavity was irrigated with the carbolized solution, after which peroxide of hydrogen, followed by iodoform and glycerine (℥ iv. to ℥ vi.), was injected. On April 15th the author found his patient in a very gratifying state, although complaining a little of his cough. As soon as the nozzle of the syringe was introduced into the wound he began to cough, but this was nothing unusual, as the same difficulty was experienced every day. The surgeon stopped for a moment, which gave the patient relief, and began again very gently to remove the pus. This time the cough became violent; the patient became cyanotic, and his pulse could not be felt. Every means possible was tried to revive him, but with no result; he was dead. Dr. Bloch was unable to hold an autopsy, but regarded the man's death as due to shock produced by a rupture of liver attachments, with a flow of pus and water into the abdominal cavity.

Pulmonary Syphilis.—Dr. Chomationas has reported the case of a man, twenty-seven years old, who two years after an attack of influenza complicated by bronchitis, and followed by hæmoptysis, presented great debility, a Hippocratic countenance, intense dyspnœa, elevation of temperature, insomnia, anorexia, violent cough, with muco-purulent and blood-streaked expectoration, and profuse night-sweats. On physical examination no lesion was detected at the apices of the lungs, but over the middle lobes posteriorly there were evidences of consolidation and of a small cavity upon the right. The patient presented tegumentary and osseous evidences of a previous syphilitic infection, and on being interrogated admitted having had a chancre ten years previously, and having had secondary and tertiary symptoms subsequently. Examination of the sputum failed to disclose the presence of tubercle bacilli. A diagnosis of pulmonary gumma was made, and a mixed treatment with inunctions of mercurial ointment and potassium iodide in increasing doses was prescribed. The patient speedily and progressively improved, symptoms and physical signs receded, and at the end of six weeks the patient was dismissed, practically cured.

In differential diagnosis the following considerations are to be borne in mind: (1)The anatomic localization of the lesions in the lungs, tuberculosis being usually situated at the apices, syphilis in the lower lobes; (2) the microscopic examination of the sputum, the tubercle bacillus being absent in cases of syphilis; (3) the history of the patient, personal and family; and (4) the results of anti-syphilitic treatment.—*The American Journal of the Medical Sciences.*

The Treatment of Large Arterial Venous Nævi by Excision.—Dr. O'Neill advises the excision of large nævi for the following reasons: 1, all the nævoid tissue can be more rapidly and thoroughly removed, so that there is not likely to be a reappearance of the nævus; 2, there is very slight hemorrhage, and it can be easily prevented or arrested by forcipressure forceps and ligatures; 3, there is no slough left in the wound; 4, the wound heals rapidly. Two cases are cited in which the result was entirely satisfactory. To control the hemorrhage during operation harelip pins may be passed beneath the growth and a rubber ligature made to encircle the base, or the vessels may be caught with hæmostatic forceps before being divided.—*Dublin Journal of Medical Science.*

The Abortive Treatment of Erysipelas of the Face.—Dr. Talamon advises treatment of facial erysipelas by spraying with a solution of corrosive sublimate in ether, 1 in 100, preferably by means of a hand-bulb atomizer. The more forcible the spray, the shorter the time required for atomization. Attention should be paid to the delicacy of the skin, the depth of infiltration, the presence of vesicles. The formation of vesicles in consequence of the spraying is not dangerous, and as long as the affected area is small may be beneficial. The spray should be especially applied to the periphery of the erysipelatous swelling, and the surrounding healthy skin for a distance of one or two centimetres. In erysipelas of the eyelids only the adjacent parts are subjected to the action of the atomizer. After the spraying the faces hould be covered with compresses frequently moistened in boric acid solution. One or two forcible atomizations are sufficient as a rule: later their force may be diminished, and only those places are to be treated where the erysipelas threatens to advance. The pain produced by the atomization is usually moderate, and is due to the increased swelling and formation of crusts. This method may be employed on other parts of the body, but more force must be employed.—*International Journal of Surgery.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, July 1, 1893.

THE PERIOD OF INCUBATION OF THE INFECTIVE FEVERS.

THE period of incubation of the various infective fevers has been a matter of great discussion, and one concerning which definite conclusions have not been reached. A report on this subject by a committee of the London Clinical Society will be received with much interest.

The material which the report contains was obtained in response to a circular letter issued in 1889 by a committee over which Dr. Broadbent presided. The large mass of documents received was digested by Dr. Dawson Williams, one of the honorary secretaries of the committee. Dr. Williams was at the pains to go through the whole of the reports made by its medical inspectors to the Medical Department of the Local Government Board since 1878, which had been laid open to the inspection of the committee by Sir George Buchanan, one of its members. Many important facts and observations, in respect especially to diphtheria, typhoid fever, and scarlet fever, were thus obtained.

The system upon which the summaries were prepared has been to take first those cases in which the exposure to the source of infection was for a short time—a few minutes or hours—at a known date. These have been made "the basis of the conclusions drawn as to the duration of incubation; while other histories, in which only the date of the commencement or cessation of exposure to a source of infection was given, have been used for contributory evidence." The duration of infectiousness is also investigated by the light of the data supplied; and the length of time which a patient who has suffered from the disease should be isolated, the period during which a susceptible person exposed to infection should be quarantined, the liability to the retention of infection in clothes and to its dissemination by milk and water, are also considered.

The conclusions of a committee which has evidently gone over the subject so carefully are of much importance, and deserve to be presented here.

Diphtheria, two to seven days; oftenest two.

Typhoid fever, eight to fourteen days; sometimes wenty-three.

Influenza, one to four days; oftenest three to four.

Measles, seven to eighteen days; oftenest fourteen.

Mumps, two to three weeks; oftenest three weeks.

Rubeola, two to three weeks.

Scarlet fever, one to seven days; oftenest two to four.

Small pox, nine to fifteen days; oftenest twelve.

Further investigations were made with regard to the time and duration of the infective period.

Diphtheria was found to be infective during the period of incubation, attacks and convalescence.

Mumps and rubeola are also infective for three or four days before the onset of the parotiditis and appearance of the rash.

The contagiousness of measles speedily disappears, and does not continue in disinfected persons for over three weeks.

Typhoid fever is infectious from the time of onset until two weeks after the fever has gone and convalescence set in.

As is well-known, the contagiousness of scarlet fever varies greatly, but is generally continued a very long time—certainly until desquamation ceases, and sometimes as long as eight weeks.

The figures put forth by the committee of the Clinical Society will doubtless excite some discussion and controversy, but they are based on a large amount of clinical data.

THE THERAPEUTICS OF SEA-SICKNESS.

WHEN we consider the immense aggregrate of human misery for which sea-sickness is directly responsible, it is rather remarkable that it has been the subject of so little systematic investigation. There is, indeed, a rather extensive literature bearing upon this malady, as the communication of Dr. Irwin, which appeared in a recent issue witnesses. But although much of general interest has been written, there is little in all this mass that is, viewed from the practical standpoint of the therapeutist, of much real value. The reason for this neglect is probably that the study of sea sickness, except for the physiologist, seems to offer less prospect of brilliant results than does that of other more distinctly defined diseases.

Sea-sickness or kinetia—a term recently applied to all forms of motion sickness—is an essentially transient ailment, seldom outstepping the stage of mere functional derangement, and rarely dangerous to life. It is true that there are on record authenicated cases of death proximately resulting from it, but excepting the extraordinary cases of inanition observed during the longer voyages of former times, there has been reason in almost every instance to attribute the fatal result to some pre-existing organic lesion. In at least one other respect sea-sickness differs from all other ailments, for the conditions which cause it are in themselves harmless, and only disturbing so long as the system remains unaccustomed to them. Consequently, the best remedy—short of absolute cessation of those conditions—is their steady continuance until *habit* has been established, and with it immunity from further disorder. The degree of derangement is influenced by such circumstances as the susceptibility of the individual, the nature of the motion, the fortuitous condition of the weather, and not infrequently the provocative character of the sufferer's surroundings. Its duration rarely exceeds from two to three days, while in the majority of cases the tendency toward recovery shows itself, even when no special treatment has been adopted, within a very few hours of the onset. It naturally follows that in estimating the value of remedies there is in this ail-

ment more than ordinary liability to confuse the *post hoc* with the *propter hoc*, and hence the somewhat absurd enthusiasm of the recurrent discoveries of a universal specific. The experiments of these men have, as a rule, been limited to a few voyages, and have probably been conducted upon persons, many of whom were otherwise insusceptible or had already partially acquired physiological exemption.

Nevertheless, it is little creditable to our science, or to the men engaged in practice upon the large passenger steamers, from whom by this time something definite might be expected, that so little is known of the therapeutics of kinetia. It seems to be fairly well established that the initial disturbance is of the special function of equilibration, upon which, no doubt, visual impressions may exercise some influence. It is equally certain that the nausea is of secondary or cerebral causation, and not the direct result of impingement or shaking up of the abdominal or other viscera. No similar disturbance accompanies riding on horseback or other exercise of much more violent character. It seems also to be of universal experience that the remedies which are most helpful may be classed either as sedatives or stimulants—sedatives to the organs responsible for equilibration, or direct stimulants to the stomach whereby this organ is enabled to resist the influence of perverted innervation. The search for a universal specific may be regarded as hopeless, if not absurd; but a systematic study of the special forms of sea-sickness as observed during the short channel passages and during ocean transit, and conducted upon the same scientific lines as would be essential in any similar investigation, may still afford valuable guidance in the treatment of individual cases.

Besides sea-sickness itself, there are other important questions connected with sea-voyaging—such, for instance, as its effect upon the menstrual function and the condition of pregnancy, which was some years ago treated of in an essay by Dr. Irwin—which should be made the subject of continued observation by those who have the opportunity.

A NEW DEPARTURE IN SANITATION.

The Board of Health of this city has instituted a new departure which will prove, we believe, of extreme importance to the community. It has issued a circular in which it is stated that much of what is usually called diphtheria is not such, but is a relatively innocuous malady not needing stringent quarantine and disinfection. The diagnosis of true diphtheria can be made by bacteriological cultures in ten or twelve hours, and the Board of Health will hereafter undertake this work for the practitioner. It is surely a most radical proposition for the State to step in and offer to become the diagnostician of disease. There were, within a given period, 775 deaths from diphtheria and 362 from membranous croup, and this must represent six or seven thousand cases of these maladies, to say nothing of thousands of other suspicious cases. The amount of bacteriological work involved will be enormous if the profession call on the services of the Board. We shall watch the experiment with great interest. It will certainly have a valuable educational effect on the practitioner, and will stimulate him to acquire a practical knowledge of bacteriology, which will no doubt be of great service. Above all, it will put a quietus on those tiresome people who continue to reiterate that "they don't believe in germs." The example set by our Board will no doubt be followed elsewhere if it is successful. It is estimated that about one-fourth only of membranous sore-throats are truly diphtheritic.

A NATIONAL BUREAU OF HEALTH.

At a special meeting of the New York Academy of Medicine, held on June 20th, the National Quarantine Committee made a report and requested that its powers be enlarged so that it could investigate and agitate the subject of establishing a National Bureau of Health. The Committee expressed the belief that only by establishing such a board could quarantine be effectively carried out and the great questions of public hygiene and State medicine be adequately dealt with. It urged that the United States put itself on a plane with other great countries of the world in thus making public health a matter of national concern.

The Academy by unanimous vote granted the request and gave the Committee power to act in the matter. It is proposed to secure the opinions and advice of medical men and sanitarians throughout the country regarding the most effective way of establishing a national sanitary organization. A bill will be framed and submitted to the profession and afterward to the Academy.

The work thus proposed is one of great difficulty, but at the same time one of enormous importance. Few realize, as medical men can, how much unnecessary disease, misery, and suffering there is in the world, and how much could be prevented by wise sanitary precautions and a wider knowledge of the laws of health. It is right that the profession should support the Academy in its present effort, and we believe it will do so heartily. Should it fail to evolve a practicable measure of sanitary organization now, its work would not be lost, for such an organization is a necessity for a great and progressive nation and is bound eventually to come.

WHO ARE NEW YORK'S IMMORTALS?

A correspondent has asked us to name the twelve best representatives of medicine and surgery who have lived and practised in this city. The question is a difficult one to answer and we shall not undertake it except in part. There are many qualities that go to make up a great physician. Some have achieved eminence through the force and charm of their personality. They have won hosts of friends, have drawn to themselves crowds of patients, and by their life and character have elevated their profession and made a mark in the community. Others have won fame as wise and learned teachers and writers, or as brilliant operators, or through original scientific work, or as ingenious contributions to the practical side of their calling.

The name of Dr. John W. Francis would probably be mentioned as most worthy to head the roll. We should add the name of Valentine Mott more readily if he had shown a generous nature in his dealing with Sims. No one can deny to this latter a place on the list of New York's immortals; nor will any hesitate to include the names of Fordyce Barker and Austin Flint. When it

comes to selecting from such eminent deceased as Watson, Buck, Wood, Delafield, Hamilton, Dalton, Parker, choice is difficult. And perhaps we ought to go back to the last century and not ignore the rights of Peter King, Samuel Bard, and others of those times. Perhaps, after all, we should adopt a stricter rule of selection and name for perpetual remembrance only those who by their originality, industry, and inventive genius added something which was a manifest help to the profession in understanding, recognizing, or treating disease.

News of the Week.

Dr. Caleb Green, of Homer, N. Y., died suddenly, Wednesday, May 10th, of valvular heart disease, aged seventy-three. Dr. Green was graduated from Geneva Medical College in 1844, and was afterward Professor of Physiology and Pathology in that institution. He was engaged in a large practice in Homer for nearly forty-five years, retiring from active work about five years ago, but kept abreast of the medical progress and literature of the day till the moment of his death. Dr. Green was one of the early members of the American Medical Association, New York State Medical Society, New York State Medical Association (of which latter he was its first Recording Secretary), was one of the founders of the Central New York Medical Association, and Secretary for many years, and several times President of the Cortland County Medical Society. Dr. Green was a great lover of natural history, and was at different times a member of the American Association for Advancement of Science, the American Society of Microscopists, and other scientific societies. He was one of the three delegates from the New York State Medical Society to the National Convention for Revising the Pharmacopœia in 1860–70, and 1880.

American Association of Genito-Urinary Surgeons.—At a meeting of this Association, held at Harrogate, Tenn., June 20 and 21, 1893, the following officers were elected for the ensuing year: *President*, Dr. George Chismore, of San Francisco; *Vice-President*, Dr. L. Bolton Bangs, of New York; *Secretary* and *Treasurer*, Dr. John A. Fordyce, of New York; *Member of Council at Large*, Dr. R. W. Taylor, of New York.

Pan-American Medical Congress. *Section of Gynecology and Abdominal Surgery.*—All members of the medical profession are cordially invited to attend the meetings of this Section to be held in Washington, September 5th, 6th, 7th, and 8th. The sessions promise to be exceptionally interesting, many valuable papers having been contributed. Those who may wish to read papers before this Section, and who have not yet sent in their titles and skeleton abstracts, are requested to do so at once. Papers have already been contributed by a number of distinguished gentlemen from the United States and Canada. W. W. Potter, *Executive President;* Brooks H. Wells, 71 West Forty-fifth St., New York City, *English-speaking Secretary.*

American Electro-Therapeutic Association.—The third annual meeting of the American Electro-Therapeutic Association will be held in Chicago, September 12, 13, and 14, 1893, at Apollo Hall, Central Music Hall Block. Members of the medical profession interested in electro-therapeutics are cordially invited to attend. Dr. Augustin H. Goelet, *President;* Dr. Margaret A. Cleaves, *Secretary*, 68 Madison Avenue, New York.

Professor Charles Felix Michael Peter died in Paris on June 15th, aged sixty-nine years. He was Professor of Clinical Medicine in the Paris Faculty, and had long been one of the most eloquent and popular of the Faculty. He was a pupil of Trousseau's and edited the last edition of that great clinician's work.

Advice to Medical Emigrants.—A correspondent, who signs himself "Ship Surgeon," favors us with a few hints which may probably be useful to those of our readers who may be contemplating a sojourn more or less prolonged in one or other of our colonies or in the United States. In the course of his experience the writer met with many medical men who were anxious "to take the ship home for me"—in other words, they wished to return to England, but had not the means to do so. The Cape appears to be much overdone, and in South Africa generally there is a large number of German surgeons. Canada and the United States seem to be not bad places for the medical emigrant if he will go up country. The clientèle is not numerous, but the fees seem to be good. Australia, though at present commercially depressed, affords favorable openings, but the large towns should be avoided. New Zealand, some parts of it at least, offers good chances of profitable work, especially in South Island. On the whole our correspondent has not a very favorable testimony to offer in behalf of practice far afield or at the Antipodes, and is inclined to take the chances which remain for him at home.—*The Lancet.*

The Cholera.—Reports from Mecca show that the cholera is raging to an almost unparalleled extent, even for that hot-bed of epidemic disease, 830 deaths having occurred there in the four days ending June 20th, 445 on Sunday, June 25th, and only one less than a thousand on Monday last. This is the largest number reported during the present epidemic, but there is no reason why it should not be exceeded except that the material for the disease to work upon must become exhausted in the course of time, notwithstanding the fact that the pilgrimage to Mecca is very large this year. The latest advices from Russia indicate that the disease is diminishing in that empire. There can be little doubt, however, that cholera prevails to a considerable extent throughout France, although the authorities are pursuing the foolish, if not criminal, course of attempting to conceal the extent of its ravages. Cases are reported from coast towns in both the northern and the southern portions of the country, and the fact that the authorities in Montpellier and elsewhere are voting large sums for the building of temporary lazarettoes for the reception of cholera patients bears witness to the prevalence of the disease in those places. Cases are reported from Alais, Nantes, Toulon, Hyères, and Cette, and the disease exists also in Malta and Cephalonia in the Mediterranean, and in Catalonia, Spain. The reports from Hamburg are more cheering, no new cases having occurred there during the week ending June 23d.

Dartmouth Medical College.—The annual opening address will be delivered this year by Dr. C. L. Dana, of New York, on July 13th.

Harvard Medical School Association.—The annual meeting and dinner of the Association was held on June 27th.

Columbia College.—At the one hundred and thirty-ninth Commencement of Columbia College, held at the Carnegie Music Hall on June 14th, the degree of M.D. was conferred by President Low on 104 graduates of the Medical Department of the College of Physicians and Surgeons of New York.

Local Anæsthesia.—Hacker, in his lectures, quoted from Schleich, at the last Surgical Congress, on the "so-called infiltration-anæsthesia," remarking that this was a very plausible theory whereon a reasonable explanation could be advanced in favor of many local applications for surgical operation. Common salt, when thrown into the intercellular tissue, will produce such a diffuse effusion that any kind of cutting may be undertaken without pain. This preparation (in a 0.2 per cent. solution) with a very small quantity of cocaine will make an excellent anæsthetic, and one that Hacker frequently uses, in the form of

℞. Aquæ destill.	100
Cocaine	0.1
Chlornatrium salt	0.2

M.

Injections with this solution must be used several times to produce the necessary œdema, after which a painless operation may be undertaken. If the insertion of the needle is to be made painless, it may be previously dusted with ethylchloride.—*Medical Press.*

Faith Cure in Diphtheria.—A little girl in this city was attacked with diphtheria. She received no medical attendance, but was treated by a faith-cure preacher. The patient died, and an investigation has been instituted to determine the responsibility of the parties.

The Therapeutical Value of Animal Extracts.—In an address delivered recently before the Boston Medico-Psychological Association, Dr. C. L. Dana said (*Boston Medical and Surgical Journal*): "It may interest you to hear the results of my own therapeutical experience in this line during the past eight months. Since July, 1892, I have been using various animal extracts of the thyroid gland, of the brain-tissue, also the rabic virus, and Hunter's modification B of tuberculin. I have treated the following cases by these methods: Locomotor ataxia (brain extract), 8 cases (6 treatment complete, 2 discontinued); 4 improved, 2 not improved. Bulbar paralysis (brain extract), 1 case; cured. Progressive muscular atrophy in late stages (brain extract), 3 cases; not improved. Epilepsy (brain extract, rabic virus, and testicular extract), 5 cases; 3 improved, 2 not improved. Two other cases whose course was known to me were improved. Paralysis agitans (brain extract), 1 case; not improved. Tubercular tumor of brain (Hunter's modification B of tuberculin), 1 case; not improved. Basedow's disease (thyroid extract), 1 case; symptoms increased. Dementia (thyroid extract), 1 case; improved. Pseudo-muscular hypertrophy (thymus), 1 case; result not yet known. Among these cases those in which some specific effects were obtained were cases of bulbar paralysis, locomotor ataxia, epilepsy, and Basedow's disease. The most striking result was that in the case of bulbar palsy. With regard to the use of the thyroid, I have already reported a case in point. It seems to me to be a very demonstrative confirmation of the theory that exophthalmic goitre is due to a toxine which stands in some relation to the thyroid gland. I wish, in conclusion, to say with regard to this particular form of treatment, that I have referred to it with some hesitation, owing to the decidedly bad odor attached to these methods. They have been utilized in the most sensational way by those who have sought newspaper notoriety, and reports have been made with regard to them which have been sensational and exaggerated. Nevertheless, I am so firm a believer in the rationality of this line of therapeutical investigation, that I am willing to brave some misunderstandings in connection with the use of such preparations. There is no more reason to doubt that there should be therapeutical properties in extracts obtained from animal organs; than that there should be such from vegetable organs. We might just as reasonably expect good therapeutical properties from the extract of a gland as from the extract of a root or a leaf or a bean. The remarkable results obtained from the use of the thyroid gland in myxœdema is of itself abundant justification of this position."

Montefiore Hospital.—Ground has just been broken for the new Montefiore Hospital, adjacent to the Montefiore Home for Chronic Invalids, and designed to enlarge the field of work of that admirable institution. The new hospital will be four stories high. The entire building is to be devoted to hospital uses except a portion of the first story, which will be occupied by a synagogue, the Montefiore Home and Hospital being supported entirely by the contributions of Hebrews. The growth of this institution has been remarkable. A two-story frame building at Eighty-fourth Street and Avenue A, devoted to the care of those affected with incurable diseases, constituted its humble original quarters. For some time only Hebrews were admitted; but when the spacious Home on the Boulevard was opened, in 1886, it was made unsectarian. The new building will cost $175,000, and it is estimated that it will require at least $60,000 additional to fit up its appointments.

Inoculation of Measles.—Dr. Hugh Thompson, of Glasgow, describes nine cases in which he had inoculated children with fresh serum taken from blisters on patients suffering from measles. He believes that four were rendered immune, and that in two the experiment failed. At the point of insertion of the serum slight measly-looking patches appeared in from one to two days and lasted for two or three days, accompanied with slight catarrhal symptoms. The serum is taken from small blisters, no larger than a measly patch, and used immediately and inserted by superficial scarifications.

Ecphyaditis is the name proposed by Dr. Robert T. Morris as a substitute for appendicitis. The word is a good one, as the term ecphyas already exists in medicine to describe the appendix vermiformis ceci. Ecphyaditis is also philologically the preferable word; it has the further advantage of distinctiveness.—*Medical News.*

Physicians are of Three Kinds: Hypocrites or quacks dressed as physicians form one class; physicians by common report form the second class; and physicians that really possess the accomplishments which such men should

possess, form the third class. These are the three classes of physicians that practise on earth. Those ignorant persons who, having equipped themselves with the utensils, the medicines, the books, and the bracelets of physicians and assumed their manners and conduct, acquire the title of physicians, are said to be hypocrites or quacks in the guise of physicians. Those persons who without really possessing them pretend to prosperity, fame, knowledge, and success such as true physicians have, and acquire the title of physicians, are said to be physicians by report. The true accomplishments of a physician are said to reside in those persons that have a practical knowledge of the application of drugs, and acquaintance with the medical scriptures and the affairs of men, that are celebrated for their success in treatment, that contribute to the real happiness of their patients, and that are restorers of life and strength.—*Charaka-Samhita.*

Dr. Paul Guttmann, Sanitary Councillor and Director of the Hospital Moabit, died at Berlin on May 24th, of pneumonia complicating influenza, aged fifty-nine.

Dr. James McCann, of Pittsburgh, died recently, at the age of fifty-seven years. The Board of Trustees and Faculty of the Western Pennsylvania Medical College, of which he was the presiding officer, have adopted a minute, from which we gather the following facts: He was born in 1836, in Penn Township, Allegheny County, Pa. His father served under Anthony Wayne in the war for American Independence. In early boyhood he passed his summers working upon his father's farm, and the winter months as a pupil of John G. Beatty, who taught him, in addition to the public school curriculum of that time, Latin and the higher mathematics. At the age of eighteen he went to Pittsburgh, where he spent several years as book-keeper in a business house, but, acting upon the advice of his physician, he finally decided to study medicine, and in 1858 entered the office of Drs. Thomas and John Dickson, Sr. He was graduated from the Medical Department of the University of Pennsylvania in 1863, and immediately entered the medical service of the army as assistant-surgeon of the Fifth Pennsylvania Volunteers. He continued in this service until the close of the war, when he returned to Pittsburgh and began the practice of medicine with Dr. W. C. Reiter. Two years later he received the appointment of surgeon to the Marine Hospital. He was next appointed one of the surgeons of the Western Pennsylvania Hospital, which position he held until a few months ago, when he resigned because of ill health, and accepted the appointment of consulting-surgeon. For twenty years he was one of the surgeons of the Pennsylvania, the Allegheny Valley, and other railroads entering Pittsburgh. He was an active and influential member of the Pittsburgh Free Dispensary from its inception, of the Board of Health for many years, of the Allegheny County Medical Society, of the State Medical Society, of the American Medical Association, of the American Surgical Association, and of the American Association of Obstetricians and Gynecologists, but owing to ill health he was never able to attend a session of the latter. He was one of the organizers of the Western Pennsylvania Medical College. Into this work he threw all his enthusiasm, and devoted to it all his energy and influence. In September, 1886, he was elected to the chair of Professor of the Principles and Practice of Surgery. This position, notwithstanding his failing health, he filled until a few months prior to his death. A short time ago he was unanimously nominated for appointment as "Emeritus Professor," but before this action could be confirmed by the Board of Trustees of the University death had claimed him. It was in the performance of a surgical operation, a work of charity in the Western Pennsylvania Hospital, that he received the fatal shaft from the quiver of the fell destroyer.

Johns Hopkins Medical School.—The faculty of the Johns Hopkins Medical School has completed the necessary arrangements for opening the school on October 2d next. According to the terms of Miss Garrett's gift, the school will be open to women on the same terms as men.

A Centenarian.—Mrs. Hannah Stevenson, of Brookfield, Mass., has just celebrated her one hundredth birthday. She is said to be mentally bright and active, though she has smoked tobacco and taken snuff for the last eighty-one years, to say nothing of a moderate indulgence in opium. Her husband was a minute-man in the War of 1812.

Dr. Carl Fischer, of Sydney, N. S. W., died of gangrene of the leg and erysipelas, in Chicago, June 22d.

Death of a Japanese Medical Student.—Helen Bruce, a Japanese young woman, who had come to this country for an education, and who had graduated from Wellesley College and was taking a medical course, died at the Salem, Mass., Hospital, on June 20th, of consumption, aged twenty-four years.

St. John's Guild.—The needed repairs on the Floating Hospital of St. John's Guild have been made, and the barge is ready to make daily trips. A new building has been erected for the Sea Side Hospital. Contributions may be sent to W. L. Strong, Treasurer, 501 Fifth Avenue.

The Rev. Dr. E. P. Thwing, a missionary in China, died suddenly in Canton, a few weeks ago. He was suffering from typhoid fever, and death was caused apparently by intestinal perforation.

A Physician Convicted of Murder.—Dr. G. S. Wyckoff, a physician of Western Pennsylvania, was recently convicted at Kittanning of complicity in a bank robbery. A man was killed by one of the burglars, and Dr. Wyckoff being brought to trial for the crime was found guilty of murder in the second degree.

Bees and Rheumatism.—Some two years ago an Austrian physician advanced the remarkable theory that persons who have been stung by bees enjoy an immunity from the effects of the bee-stings for varying periods, and that, moreover, the virus of the bee-sting is an infallible remedy for acute rheumatism. The latter part of the theory, according to the *Mediterranean Naturalist,* has received unquestionable confirmation from a custom of the country people in Malta. Bees are plenty in the island, and bee-stings are in such repute as a cure for rheumatism that resort to this primitive method of inoculation has been a common practice in severe cases for generations, the results having been most satisfactory to the patients.

Society Reports.

American Medical Association.

Forty-fourth Annual Meeting, held in Milwaukee, Wis., June 6, 7, 8, and 9, 1893.

(Special Report by Telegraph to the MEDICAL RECORD.)

(Continued from Vol. xliii., p. 761.)

SECTION IN MEDICINE.

THIRD DAY, THURSDAY, JUNE 8TH.

Brief Clinical Memoranda.—A paper was read by DR. H. H. DIDAMA, of Syracuse, with this title. The matters considered were as follows:

1. *An Available Catheter Lubricant.*—The physician may find himself obliged to pass the catheter, and may have no available lubricant. It is well to remember that saliva will render the catheter sufficiently slippery to insure its penetration into the bladder. It will be said that the saliva is full of micro-organisms and all sorts of impurities; but if the mouth is clean, its secretion will answer in an emergency.

2. *Facile Reduction of Prolapsed Hemorrhoids.*—The mass should be well cocainized and smeared with vaseline. Have the patient assume a squatting posture, and instruct him to bear down as in defecation. He will at first, on account of the pain, shrink from so doing, but can do so if encouraged in his efforts, which will relax the sphincter and insure the return of the mass by proper upward pressure thereon.

3. *Preparing Hemorrhoids for Injection.*—Anæsthetize the patient by the A. C. E. mixture. Dilate the sphincter well by digital force. Bring down the tumors, and ligate all those with a small pedicle by a ligature left tied in a bow-knot. Next inject six drops of a mixture of carbolic acid, one part; cocaine solution (eight per cent.), and glycerine, of each two parts. The blood is clotted in a few minutes, and this clot prevents the absorption of poisonous material. In the course of five or ten minutes the knots in the ligatures may be untied and the latter removed. The patient, on recovery from the anæsthetic, can at once get up and resume his business. The strangulated tumors will quickly shrivel up and fall off in the course of a few days.

4. *Ready Relief from Lumbago.*—This may be obtained by the use of large dry cups along the ridge of the lower spinal muscles. The cups of a conical shape, similar to a urinary deposit-glass, are preferable.

Typhlitis.—"Medical Treatment of Typhlitis and Appendicitis," by Dr. F. W. Ross, Elmira, N. Y.; "An Unusual Case of Appendicitis," by Dr. J. H. Musser, of Philadelphia; and a "Discussion of Dr. Musser's Case and of Appendicitis," by Dr. Joseph Price, of Philadelphia. The papers were not read, but a general discussion of the whole subject suggested by them was opened by Drs. McLean, of Detroit, and Price, of Philadelphia.

DR. J. J. WHITTAKER, of Cincinnati, believed that many of these cases are really tubercular in origin. The cæcum is a stagnant reservoir, into which sputa, if swallowed, are run by intestinal peristalsis. The removal of the appendix may not cure all cases of right iliac inflammation, as the latter process may recur in this locality. Such recurring cases should be referred to the surgeon. To rely on pain at any one point as an indication of the presence of pus is a fallacious guide, as in most cases pain is not circumscribed, but diffused.

DR. JOSEPH HOFFMAN, of Philadelphia, stated that statistics showed that, in 18,000 cases of right iliac inflammation, absolute disease of the appendix existed in 91 per cent. and typhlitis in only 9 per cent. We must distinguish, between cases of typhlitis, those due to simple impaction (fecal or otherwise) and those due to peritoneal twists. The appendix has a mesentery of its own, and the cæcum twists in a manner peculiar to itself. We have therefrom inflammations of simple congestion with pain, tympany fever. These cases are often called typhlitis, and recover under the use of opium, though calomel and a saline are preferable. They are *not* cases of true appendicitis. Cases with obstruction or impaction may get well without operation, just as a bullet may become encysted and do no harm. An accumulation of pus here may burst open in the loin or groin or (as he knew to occur in one instance) be spat out. The origin of the appendix from the gut is constant, but the revolutions and twists of the latter may place it in various positions. If the exhibition of a saline, by clearing out the bowel, does not relieve the pain, the accumulation of pus is strongly suggested.

DR. L. S. MCMURTRY, of Louisville, believes that cases of appendicitis are far more common than is generally supposed. Many of the fatal cases are recorded as peritonitis on the mortality reports of large cities. In males ninety per cent. of all cases of peritonitis are, he believes, cases of appendicitis.

More has been learned about the pathology of the abdominal contents by operation during life than by post-mortem examination. Many cases of peritoneal inflammation of all kinds are the results of appendicitis. Of course, he does not advise operation on all cases, but it is a fact that a majority of them come either to an operation or die without. The majority of cases do not eventuate in recovery by expectant treatment.

DR. H. A. HARE, of Philadelphia, believed that opium was not to be commended in this class of maladies. It masks the pain, tenderness, and fever, so that the collection of pus proceeds unnoticed. Patients should be kept on a pre-operative diet, so that, if operation is hurriedly called for, it can be undertaken without at all disturbing the bowels. Ice, hot and cold injections, may be used to combat the inflammatory process. All purgatives should be avoided before operation. Dr. Hare does not believe that all cases of peritonitis in the male are of appendix origin. He quoted the statistics, published some years ago by Dr. Fitz, of Boston, showing that the death-rate after operation was greater than when the cases were treated by medical means.

DR. CHARLES A. L. REED, of Cincinnati, quoted cases to show that all physicians do not recognize these cases early enough to give the surgeon a fair chance if he is called upon to operate. Recurrent cases ought to be operated upon without reference to the existence of pus, so that a procedure of election may be undertaken at the proper time, and not when the patient is in a hopeless condition. He believes that there is no such thing as "idiopathic" peritonitis, and that future years will show, on account of the early recognition of the gravity of cases, a marked improvement over Dr. Fitz's old figures.

Diphtheria.—DR. J. B. MURFREE, of Murfreesboro, Tenn., read a paper on this subject. He gave a general survey of the history of the disease, with special reference to its introduction into the United States.

DR. JENKINS, of Iowa, in discussing the treatment of this disease, stated that he prefers the local application of carbolic acid or persulphate of iron solutions. The latter coagulates the albuminous exudates, contracts the vessels, and shrinks the membrane off. If the larynx is affected, he places much value on calomel.

Aspiration in Acute Pleuritis.—DR. E. J. C. MINARD, of Brooklyn, read a paper on "Early Aspiration in Acute Pleuritis." While calomel, opium, veratrum, and poultices all have their value in the therapy of this affection, she believes that early aspiration has more than a merely palliative effect. She finds the diagnosis sometimes difficult, as accompanying congestion elsewhere may cause far more pain than that of the initial malady. Thus she has seen a case of pleurisy with intestinal engorgement where the pain attendant on the latter was so great as to suggest appendicitis. She has seen aspiration of ten ounces of fluid reduced the temperature from 104° to 98.3° F. in three hours. The general practitioner should be prepared to do the operation.

DR. J. M. ANDERS, of Philadelphia, thought that in

these cases the initial exudation of fluid filled the chest about one-half. Then in twenty-four to forty-eight hours there was a sudden filling of the cavity to its maximum. As regards the indications for operation, urgent dyspnœa (even orthopnœa), especially at night, is a most important feature. When it occurs, aspiration should at once be made, even though there is some fever and embarrassed circulation. The relief, however, is apt to be but temporary, as the fluid reaccumulates. Fever means an active inflammatory process and progressing fluid leakage, not a mere transudation, but a true inflammatory exudation. If there is no fever, how long shall we wait before tapping? He thought not over ten days. Now, we must remove only a portion of the fluid at once, and repeat the tapping until the tendency to recurrence seems to be overcome. The effect of suddenly taking away too much pressure from the displaced heart may lead to syncope.

Dr. Scott, of Cleveland, thought that large exudations were more apt to occur in subacute rather than in acute cases.

The Detection and Significance of Carbohydrates in the Urine.—Dr. Charles W. Purdy, of Chicago, read a paper with this title. He discussed the various chemical tests for glucose, and pointed out the fallacies of each. Sugar is always present in minute amount in healthy urine, but does not react to our ordinary chemical tests. Hence its significance is physiological, and not clinical. Many causes will produce glycosuria. His favorite test-fluid is made as follows:

Sulphate of copper (pure)	48 grains.
Caustic potash (pure)	144 grains.
Strong ammonia, U. S. P.	9 ounces.
Glycerine (pure)	6 drachms.
Distilled water	to 20 ounces.

The solution should be prepared by dissolving the copper sulphate in part of the water and adding the glycerine. In another portion of the water dissolve the caustic potash. Mix the two solutions and add the ammonia. Finally, with distilled water bring the volume of the whole to twenty ounces. Keep well corked, and filter in two or three months if the solution becomes in any way cloudy.

The principle upon which the application of this test depends is the fact that a definite quantity of the solution is reduced upon boiling by a definite quantity of grape sugar, causing complete disappearance of the blue color, and leaving at the exact point of reduction a brightly transparent and colorless fluid. Thus ten drachms of this solution are reduced upon boiling by exactly one third grain of grape sugar.

Dr. N. S. Davis, Jr., of Chicago, corroborated the value of this test-fluid. He thought, however, that the Fehling solution made and kept in different bottles for each ingredient perfectly reliable.

Brandt Method of Treating Typhoid Fever.—A discussion on this subject was opened by a paper by Dr. Chr. Sihler, of Cleveland. He believed that this method ought to be, can be, and will be used in private practice as well as in hospital. In three years and a half he has given over five thousand baths in ninety-five cases, without accident or incident. Most of his cases have been among laborers and artisans, who have carried out the method just as well as those in better circumstances. As to objections, the patient at first rebels, but sleeps so much better after the bath that he comes to like it. The method seems complicated to some and to others dangerous, but it is found that a patient so treated comes through the disease with his nervous system in a much better condition and is spared much of the usual tedium of convalescence. The bath-tub can be portable and sent by the physician to the house. The latter should have one or two nurses trained in the special technique, who can give the necessary instructions to the family, who can then take charge of the case themselves. A bath at 68° F. for fifteen minutes is better than one at 70° F. for twenty minutes, for it is in the last five minutes in which the shivering is especially noticeable. The first bath should be given as early as possible and Brandt's original instructions should be followed to the letter. Don't counteract the good effects of the baths by giving too much whiskey.

A paper on the same topic, by Dr. W. Gilman Thompson, of New York, was read by the Secretary. He gave the records of ninety-five cases, treated in the New York and Presbyterian Hospitals. He prefers to give half an ounce of whiskey fifteen minutes before each bath, and lays much stress on the accompanying cold affusions on the head. The bath is followed by a glass of hot milk containing malt extract, and a cold compress may remain laid on the abdomen. In nervous patients the first bath may be begun at 90° F. Menstruation, and even pregnancy, need not contraindicate this method. Out of the 95 cases there were 7 deaths, 4 from intestinal perforation and peritonitis, 2 from hemorrhage, and 1 from pneumonia. Tubbing has not shortened the entire duration of the disease nor lessened the frequency of relapses, but complications have been far less numerous. In one case there were pains in the hands and feet, suggesting the lesions of peripheral neuritis; but the same pains occurred in typhoid cases not bathed, and could in nowise be attributed to bathing.

Typhoid Fever.—Dr. James B. Herrick, of Chicago, read a paper giving an analysis of "One Thousand Cases of Typhoid Fever," going especially into symptomatology. As to treatment: rest, diet, sponging, ice pack and coil were used, also antipyretics. The mortality of the cases was about seventeen per cent.; but of seventy-six cases from private practice only one had died.

The general topic suggested by the last two papers was discussed by Dr. Joseph Eichberg, of Cincinnati. He was not prepared to give up everything for the Brandt method. In his hospital practice antifebrine had given better results than the bathing.

Dr. Loughran, of Indiana, preferred intestinal antisepsis, which he claims to secure by naphthalin.

Dr. J. M. Anders, of Philadelphia, thought that, if shivering came on early in the bath, the patient should be at once removed. He advocates the Brandt method and condemns the coal-tar preparations.

Dr. Quine, of Chicago, does not believe that we should tamper with the natural course of temperature. He believes that tubbing lengthens out the disease and makes relapses more common. He has seen death occur in the bath, and also one case of catarrhal pneumonia develop. Also he thinks that the coal-tar series predispose to relapses and intestinal hemorrhages.

The paper was also discussed by Drs. Scott and Herrick, of Cleveland, Jenkins, of Iowa, and by the Chairman. The opinions of the Section seemed to be about evenly divided as to the advisability of bathing.

Fourth Day, Friday, June 9th.

The Association of Diseases and Morbid Processes.—A paper with this title, by Dr. H. A. West, of Galveston, Tex., was read by the Secretary. The paper discussed the histories of various cases where an autopsy revealed the existence of processes to the existence of which no clue was given by the clinical features of the case. Special stress was laid upon the fact that many diseases, from which recovery seems perfect, leave the body in a condition of great susceptibility to the action of further morbific agents. A classification was also made of the various morbid processes which are found associated with each other.

In discussing this paper, Dr. Charles W. Dennison, of Denver, noted the common association of fibrosis with tuberculosis. He believes that those masses of new deposit which we call "tubercle" are in reality the "prison vault" of the bacilli. The latter always signifies or induces an increase of connective tissue and cell-proliferation. Tuberculin has a contractile influence on these tuberculous masses, and not a softening influence unless

used in such large doses as to cause necrosis, a thing which he studiously avoided.

Election of Officers.—The following officers of the Section were elected for the coming year:

Chairman, Dr. H. A. Hare, of Philadelphia; *Secretary*, Dr. W. H. Washburne, of Milwaukee; *Executive Committee*, Drs. I. E. Atkinson, of Philadelphia, N. S. Davis, Jr., of Chicago, and C. G. Stockton, of Buffalo.

During the session the following papers were read by title: "Some Thoughts on the Differential Diagnosis of Chest Disease," by Dr. J. G. Truax, of New York City; "The Treatment of Pyrexia," by Dr. Jas. Witherspoon, of Columbia, Tenn.; "The New Chemistry of the Stomach as a Means of Diagnosis and a Guide to Therapeutics, based upon the Results of One Thousand Analyses of Stomach Fluids," by Dr. J. H. Kellogg, of Battle Creek, Mich.; "The Value of Belladonna and Strychnine in Conditions of Circulatory Depression," by Dr. H. A. Hare, of Philadelphia, Pa.; "The Management of Hysteria by the General Practitioner," by Dr. W. F. Rochelle, of Jackson, Tenn.; "Hæmatoma Auris," by Dr. H. A. Matzinger, of Buffalo, N. Y.; "Aneurisms considered Medically rather than Surgically," by Dr. O. C. McNary, of Leavenworth, Kan.; "Insanity of Physiological Epochs," by Dr. A. W. Hurd, of Buffalo, N. Y.; "A Case of Cancer en Cuirasse, with Report of an Autopsy and Illustrations," by Dr. J. B. Marvin, of Louisville, Ky.; "The Cancer Parasite from a Microtechnical Stand-point," by Dr. A. P. Ohlmacher, of Chicago, Ill.; "Studies in Immunity," by Dr. D. N. Kinsman, of Columbus, O.; "A Preliminary Report on an Inquiry as to the Frequency of a Form of Kidney Degeneration in which Albuminuria may not be regarded as a Symptom," by Dr. D. D. Stewart, of Philadelphia, Pa.; "The Origin and Clinical Significance of Uric Acid," by Dr. Victor C. Vaughan, of Ann Arbor, Mich.; "Experiments with Trional as a Hypnotic," by Dr. W. C. Krauss, of Buffalo, N. Y.; "Typhoid Fever," by Dr. M. J. Crouch, of Union, Ky.; "A Case of Fever of Undetermined Type," by Dr. Starling Loving, of Columbus, O.; "The Treatment of Diabetes Mellitus by Jambul (Sygygium Jambolaneum)," by Dr. James Tyson, of Philadelphia, Pa.; "Heat in the Treatment of Disease," by Dr. Chas. H. Shephard, of Brooklyn, N. Y.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

First Day, Tuesday, June 6th.

The Section limited the number of papers to be read to forty, which had compelled the Chairman to reject some from very able men.

Some General References to Obstetrical and Gynecological Advancement was the subject of the address by the Chairman, Dr. John Milton Duff, of Pittsburg. He thought the Section should publish a volume of proceedings, more especially in order to put on permanent record the discussions. The specialist should be an evolution from the general practitioner. Too many of our recruits had not had sufficient experience to be taken into the ranks of the Section. Sufficient instruction was not given in obstetrics and diseases of women in teaching institutions. He believed it was no exaggeration to say that fifty per cent. of graduates had never witnessed a labor nor introduced a speculum. We should demand of teaching institutions that they appoint professors for their broad ability to teach, and not because of their ability to purchase position. Many young men showed a willingness to do cœliotomy who were unable to repair a vesico-vaginal fistula or determine the diameters of the pelvis. The general and special medical journals were steadily improving in quality; and Dr. Duff said he hesitated, through fear of showing his inferiority, to make any criticism in this direction. He had heard, however, an expression of opinion on the part of some that there ought to be more leading articles from the editors.

Hysterectomy, he thought, had been shown by statistics to be a justifiable procedure in cancer of the uterus. Fully ninety per cent. of cases coming to the gynecologist were, however, inoperative; and this suggested the responsibility of early diagnosis by the general practitioner.

Referring to operations on the insane, Dr. Duff said it was absurd for editors or others to suggest that gynecologists seriously considered removing the appendages for all cases of insanity. But insanity was not a panacea for pain, and insane women should not be denied the benefit of surgery for disease which was given her well sisters. It should be regarded as a crime against society at the present time for those mentally unsound to propagate the species. The copulative act should be performed only in the best physical and mental condition of both father and mother.

The field opened up by the revival of pubectomy was alluded to. The rate of mortality from puerperal sepsis was now lower in institutions than in private practice—a suggestive lesson to general practitioners and obstetricians. Exploratory operations were not without danger, and should be undertaken with precaution.

The Causes of Diseases of Women.—Dr. Charles P. Noble, of Philadelphia, read a paper on this subject, treating of it in a systematic way, dividing the causes as follows: 1, Imperfect development of the sexual organs; 2, gonorrhœa; 3, pelvic inflammation following childbirth; 4, lacerations due to childbirth; 5, miscellaneous causes—such as constipation, erroneous methods of living, bad dress. Among the causes of imperfect development one could recognize forcing at school, want of bodily exercise, work in factories, etc. Absence of menstruation or scanty flow was seen in some corpulent women; but he was unable to say what was the relationship.

This class of patients were apt to show imperfect development of the general system, to have chorea, etc. Exercise in the open air, iron, arsenic, tonics, were indicated.

Dr. Howard A. Kelly, of Baltimore, had given this subject of preventive disease in women much thought, and believed a book could well be written upon it. In many instances the cause of imperfect development of the genitals and of the general system was to be traced back of the child to the poorly nourished and ill condition of the mother before and after conception. Gonorrhœa in children was not an uncommon first cause of disease in women. Tuberculosis had been found as the cause in one out of five of his operative cases of pelvic inflammation.

Dr. E. P. Davis, of Philadelphia, thought neuralgias during the pregnant state, especially of the sciatic type, were often avoidable by early attention to constipation and general habit.

Dr. Joseph Price had found vaginitis in infancy not an uncommon cause. Gonorrhœa was now a frequent source of pelvic inflammation, while it was unusual before the wide development of the railroad system. Referring to the favorable statistics of some lying-in institutions, regarding the mortality from puerperal sepsis, he said they did include the mortality from other causes. In an institution with which he was connected, not a child had been lost among 1,300 births.

Dr. Reed, of Ohio, had found the usual cause of one daughter only in a family of several failing to menstruate at the usual time to be due to imperfect development. The doctor erred in telling the mother it would be all right after marriage; for unless measures were taken for better development, the marriage would be sterile—the patient would suffer.

Dr. Carstens, of Detroit, did not believe gonorrhœa so common a cause of pelvic inflammation. The more frequent cause was the vicious habit of women producing abortion with dirty darning-needles, etc.

Dr. Hoff, of Ohio, had practised nearly half a century, and had not seen half a dozen cases of gonorrhœa in daughters. Perhaps it was not so common as it had been represented in Philadelphia.

Dr. Hoffman, of Philadelphia, did not believe the vaginitis of children was often of gonorrhœal type. He had often found tuberculosis in the pelvis, and believed it frequently followed pus collections, if it was not caused thereby.

Dr. Sell, of New York, had observed gonorrhœa in children, and even in a minister's family from supposed moral country districts: he would not mention the State.

Dr. McMurtry, of Louisville, thought some doctors were yet guilty of causing much disease among women by using caustics to the cervix, etc.

Puerperal Hemorrhage.—Dr. James P. Kerr, of Pittsburg, read the paper. The importance assumed by puerperal hemorrhage among medical and surgical subjects was due to its frequency, and the fact that, unless it was met by speedy and efficient remedies, it would end fatally. Practitioners were too apt to consider all cases of labor as normal, and not to make any preparations for this accident. One should obtain all the information possible regarding whether there was a family history of bleeders, of individual menstrual peculiarity, hemorrhage at previous confinements, etc.

The author mentioned causes, which, naturally, were various, then related one personal experience, and passed to the general subject of treatment. His case was that of a woman, to whom he was called for the first time after the beginning of hemorrhage. She gave a good history, having had no trouble at previous confinements, but her feet were swollen and albuminuria was not improbable. Without warning, a sudden gush of blood took place, and when he arrived she was in collapse and died within an hour from the commencement of the hemorrhage. The treatment had been podalic version and delivery, general and uterine stimulants, and uterine manipulations. The uterus did not contract in spite of the use of ergot, hot water, ice, vinegar, etc. The exact cause of the hemorrhage was not learned. Severe post-partum hemorrhage was generally a preventable accident by skilful management of the third stage of labor. Attention should be given to securing contraction of the uterus by carefully following the organ down with the hand when the child was expelled. If the uterus were soft and flabby, give a preparation of ergot. Misrachi claimed that caffeine acted more readily than ergotine, especially if the patient had lost blood. If the patients were known to be bleeders, J. M. Duff gave strychnine, $\frac{1}{60}$ to $\frac{1}{30}$ gr., three times daily for about two months before term. Bossi recommended hydrastis canadensis. Murray advocated plugging the vagina during hemorrhage if the os were undilated, but the author feared hemorrhage would go on within the womb. When the uterus was empty it might be packed.

Kocher, he said, recommended a method which was at least novel: invert the uterus, put a rubber band around the neck, remove the band after six hours, and replace the organ. If the circular artery were injured, it should be ligated. Plugging of the vagina was good treatment in hemorrhage from the cervix, the seat of carcinoma. Transfusion was useful as a palliative.

Dr. Barker, of Philadelphia, had learned from an experience with one case that ice, hot water, and ergot were entirely inefficient in severe post-partum hemorrhage, and their use led to waste of precious time. He would recommend the tampon. In slight hemorrhage the measures first named would effect control. He thought the number of cases seen by one was in inverse ratio to his experience in midwifery. The youthful doctor was apt to be meddlesome through over-anxiety.

Dr. E. P. Davis said it was very difficult for a serious hemorrhage from the uterus to continue while one kept one hand in the uterus and compressed from without with the other. In England they were again discussing compression of the abdominal aorta.

Dr. Morehead, of Wisconsin, had saved a case, twenty years ago, by compressing the abdominal aorta with the hand in the uterus, re-enforced part of the time by the other hand pressing upon the uterus from without. Another case was seen by him later, and treated successfully in the same manner.

Dr. Montgomery, of Philadelphia, had found strychnia excellent in persons showing tendency to hemorrhage, and also in a case of hemorrhage until shock had passed. He doubted the practical value of compression of the abdominal aorta, especially with the hand in the uterus, as part of the blood-supply came from the ovarian arteries, which arose higher on the aorta. The benefit experienced in Dr. Morehead's cases was probably due to the presence of the hand in the uterus, just as it was in other cases to gauze.

Second Day, Wednesday, June 7th.

The Routine Practice of Administering Ergot after the Third Stage of Labor.—Dr. T. Ridgway Barker, of Philadelphia, read a paper in which he advocated the routine practice of administering ergot after the third stage of labor in order to avoid hemorrhage and its accompanying dangers. It had been objected that it caused more frequent contractions and suffering. While, the first two hours, the discomfort was somewhat increased, this was more than offset by the advantages. Its use insured the woman against possible uterine relaxation. It reduced the size of the uterus and contracted the blood-vessels in the walls. It closed the uterine sinuses. It reduced the area of the placental site and diminished the danger of infection. It shortened the duration of the after-pains. It hastened the physiological process of involution. The author preferred the administration of ergotine in tablet form, one-fourth of a grain. He had never known its use to be productive of harm.

Dr. Joseph Eastman, of Indianapolis, objected to the routine use of ergot, because it substituted tonic (unnatural) for clonic (natural) uterine contractions. He was confident he had seen subinvolution of the uterus produced by the routine use of ergot. Strychnia permitted of more nearly the physiological action of the uterus.

Dr. J. Murphy, of Wilkesbarre, had found mistletoe stop hemorrhage where ergot had failed.

Dr. Duff, the Chairman, had read a paper on the same subject at the last meeting, taking the opposite view and opposing the routine use of ergot. It caused abnormal to take the place of physiological uterine contraction in ordinary cases in which no interference was indicated. Nature should not be forced when she was doing her work normally. The obstetrician could usually tell when hemorrhage or trouble was threatened, and strychnia would often be found preferable to ergot.

Dr. C. S. Bacon, of Chicago, had ceased the routine administration of ergot, because it had tended to dry up the milk secretion. Another objection was the uncertainty of its preparation.

Repeated Extra-uterine Pregnancy, with Report of a Case.—Dr. George J. McKelway, of Philadelphia, read the paper. He advocated the removal of the appendages on both sides in all cases of tubal pregnancy on one side, because of the likelihood in such cases for subsequent pregnancy to be also extra-uterine, subjecting the patient to the attendant dangers and the necessity for submitting to a second operation. The case related was of this nature, and many others similar found in literature were cited. In at least one there was evidence of double pregnancy in the same tube on different occasions. Lawson Tait and Bland Sutton claimed that many cases, heretofore regarded as hæmato-salpinx and pelvic hæmatocele, were really the result of tubal pregnancy. This fact, and the well proven ones of repeated extra-uterine pregnancy, showed the likelihood of disease on the opposite side, and pointed to the propriety of removing both tubes and ovaries.

Dr. H. J. Boldt, of New York, related a case, to impress the view which he held in opposition to the author, that where the opposite tube and ovary were healthy, they should be allowed to remain. Where, however, they were diseased, they should be removed in the class

of cases under discussion, just as during an operation for pyosalpinx or other condition.

Dr. Eastman, of Indianapolis, objected to operating on healthy appendages, because on one side there might be tubal pregnancy, and said the danger of having to submit to a second operation was more than offset by the enhanced danger of the double procedure at the same sitting.

Dr. H. T. Hanks, Howard A. Kelly, C. R. Reed, C. P. Noble, Carsten, and McClaren favored removal of the appendages on the opposite side when they were diseased, but objected to the procedure when there was no evidence of disease.

Dr. Kelly thought especial attention should be given the pathological condition. The studies of his assistant, Dr. Williams, pointed to crypts or diverticula in the tube, sometimes observable only under the microscope, as the cause of tubal pregnancy, the ovum becoming lodged in one and unable to pass to the uterus. But we could not say that this condition existed, making tubal pregnancy probable, in a tube which appeared to be normal, simply because tubal pregnancy had occurred on the other side.

Dr. O. B. Will, of Peoria, referred to the potency of the tubes as bearing on the etiology.

Porro *vs.* Cæsarean Section.—Dr. J. H. Carsten, of Detroit, had reported a successful Porro-Cæsarean section, in the *American Journal of Obstetrics*, last year, and it was peculiar that he should be able to report another within six months. The second patient was of German parentage, and in 1891 Dr. Carsten had helped to perform craniotomy upon a dead child. She was told of the danger of a second pregnancy, but kept it secret until two weeks before term. She was taken to the hospital, and at the commencement of labor prepared for operation. The bag of waters was first ruptured, and then the usual incision was made. The uterus was rolled out *à la Müller*, an elastic ligature was applied, then the uterus was quickly opened, and a child weighing eight pounds was removed. It was yet undecided to do Porro operation; but as all the physicians present were in favor of it, he applied the clamp and removed the uterus and ovaries. The after-treatment was like in any other cœliotomy, and the recovery was smooth. The only question in his mind was whether he should have done the Porro or have left the uterus. Was it right to deprive the woman of the possibility of becoming pregnant again, since she desired a child, and the one might possibly die? Should she be subjected to the dangers of repeated Cæsarean section? Was it right to propagate the hereditary tendency to deformity?

Dr. Carsten was inclined to do Porro for three reasons: 1, It could be quickly performed; 2, it was less dangerous; 3, the woman's future was free from any such dangerous operation.

A Successful Case of Cæsarean Section.—Dr. Giles S. Mitchell, of Cincinnati, read the history of the case. The paper stated that the operation was demanded because of a hard tumor filling the sacral curve, narrowing the conjugate at the brim to one and one-half inch. The nature of the tumor was not named. The patient refused to go to a hospital, and the operation had to be performed in tenement surroundings. He did not wait to try forceps, but operated soon after commencement of labor. Thirty minutes were consumed. It was usual to make the abdominal incision so that only one-third extended above the umbilicus; in his case two-thirds lay above the umbilicus.

He also varied from the custom, and used but one line of sutures in the uterus, that through the peritoneal covering—continuous, instead of interrupted. The quickness of the operation, due to the manner of operating, and not interfering with the appendages, contributed to the recovery, as did also the fact that there had been no injury to the soft parts by vain attempts at delivery with forceps. He thought that at present craniotomy on the living child was never justified.

Dr. Noble, of Philadelphia, had done Cæsarean section twice successfully; had been connected with two other cases, also successful. He had done one symphyseotomy successfully; had witnessed another case, which was also successful; and he believed symphyseotomy should supplant Cæsarean and Porro where the diameter was not under two and three-quarter inches.

There was no reason why a rachitic woman should be subjected to Porro because of hereditary propagation. She could bear healthy children like any other woman.

Dr. Joseph Price thought the indications were different in Porro and in Cæsarean section. He had done Porro six times, always in tumor. All the patients recovered.

Methods of Removing the Uterus for Fibroids, with Cases.—Dr. J. N. Martin, of Ann Arbor, read a paper on this subject. Of thirteen cases of hysterectomy operated upon by him for fibroids, two patients died—one, because of the size of the tumor and seriousness of the operation; in the other, because of supervention of cerebral trouble with hemiplegia.

In six cases the stump was treated intra-peritoneally, four called for total extirpation.

As to methods, the author claimed no originality. The method must be adapted to the case, and a combination might be best. He approved of that method, if conditions permitted, which left the cervix with its stump, treated intra-peritoneally, for the following reasons: 1, it left a stronger floor for the pelvis without a cicatricial mass, and left the vagina in better condition than when the cervix, too, was removed; 2, it was better than fixing the stump in the abdominal wound, as it permitted free dilatation of the bladder, and there was no contraction. Recovery was more rapid, as there was no sloughing mass left to suppurate or interfere with union.

The vagina was left in better condition than after Byford's method, as in the latter he believed the cervix and tissues about were so twisted out of shape as to leave them to separate. But if the intra-peritoneal method were to be adopted, it was necessary to control hemorrhage, do an aseptic operation, and drain through the posterior cul-de-sac into the vagina.

Methods and Material in Abdominal and Pelvic Surgery.—Dr. Joseph Price, of Philadelphia, read a paper with this title. It was composed largely of surgical moral epigrams. The openings were many and wide for difference of opinion. Ours was a great universe, in which we were all pupils, gaining with a humiliating tardiness the lessons of our science. We were not so tied to our present methods that we would not welcome better ones. The responsibilities of our profession were too grave, our work, when wisely and skilfully done, too beneficent in its character, for us to go on repeating errors. There was no time when we were so happy in being at home as when our critics called. New and powerful impulses were carrying forward the profession. Reverence for antiquated methods had lost its force. We accepted only those facts which withstood the severest clinical tests.

To elicit discussion, Dr. Price gave his opininn upon some disputed points. Some, briefly stated, were the following: Vaginal hysterectomy for diseased appendages was a very imperfect and dangerous procedure in the hands of every one. The adhesions, omental and intestinal, commonly found in the removal of all adherent forms of disease, must be dealt with from above. Hysterectomy for metritis and for prolapsus was unjustifiable.

In cases of peritonitis, treatment must be prompt, radical, and thorough. Seek the cause; the abdomen once open, there should be no hesitation in removing it; then establish drainage.

Opium should be absolutely avoided. The one saving method of any variety of general peritonitis was abdominal section and irrigation. Many lives had thus been saved. Leave no operation incomplete. Close holes into the intestine, should they be made during breaking up of adhesion. Pain after operation was likely to be due to distention.

Give salines before, and distention would not be likely to follow operation. In operations, damp, cold rooms and corridors were to be avoided. It was important to use warm, dry blankets. An operating-table made of manifold coils of steam pipe was a simple and perfect way of treating shock. Unnecessary prolonged anæsthesia should be avoided. It mattered not how chloroform killed, it did so oftener than ether, and should not be used. He protested against rude, rough handling of patients as a Kentuckian would a package of fine old bourbon. The operator should have an accurate knowledge of his materials. He condemned catgut, and used fine silk.

Officers Elected.—At this juncture, Dr. Joseph Eastman, of Indianapolis, was elected Chairman, and Dr. McKelway, of Philadelphia, Secretary of the Section for the ensuing year.

The papers by Drs. Martin and Price ware discussed together, the remarks being directed chiefly to the methods of operating for fibroid tumors. Most of the gentlemen emphasized the stand taken by Dr. Martin, that the procedure should be varied according to the case. Much was said about intra-abdominal but extra-peritoneal method of treating the stump, leaving the cervix and covering it with flaps. It was participated in by Drs. Eastman, Noble, McLaren, Reed of Cincinnati, Boldt, H. A. Kelly, H. O. Marcy, McMurtry, Humiston, C. R. Reed, Carsten, E. P. Davis, and the authors.

Dr. Reed, of Cincinnati, used chloroform, and said he had never seen but one patient die on the table in anæsthesia, the mixed vapors being used. When chloroform killed, he knew it; when ether killed, it was by pneumonia, nephritis, or uræmia. He had had four deaths in which ether was the cause some days after operation; none from chloroform.

Dr. Boldt advocated catgut.

Dr. Kelly would never use it again, having lost by sepsis carried by it four cases after a long series of successful cases of cœliotomy. He now used only fine silk.

Dr. Carsten had come to use only kangaroo ligature.

The discussion revealed a growing distaste for attaching some supposed inventor's name to a given method of operating. Dr. Marcy expressed his feeling on the subject by allusion to the story of the father who said to his boy: "Horatio, Horatio, don't attach your name to a speculum and have it go dangling down the ages like a tin can fastened to a dog's tail, for I have been your father."

Dr. Price said Leidy was once lecturing on the kidneys, and forgetting the name of certain little bodies, a student remarked, "Malpighian." "Oh, yes, I wish old Malpighi was in hell!" It was results posterity would be interested in, not names.

Dr. Price was the only one who advocated rather warmly supra-vaginal hysterectomy and fixation of the pedicle in the abdominal wound; the reason being that out of over forty cases he had lost none. He would do total extirpation in preference to leaving the cervix as in what had been spoken of as Baer's method, although it had been described before Baer had done it.

Third Day, Thursday, June 8th.

Ventral Hernia following Laparotomy—Its Cause and Means of Prevention.—Dr. H. O. Marcy, of Boston, presented a paper on this subject, and said: "Although we live in the era which is denominated revolutionary in the science and art of surgery, he who proposes modifications to long-established rules should do so only after the most convincing evidence of their manifest advantage and importance." It was admitted that about ten per cent. of all laparotomies resulted in ventral hernia; and in order to prevent this, it was quite the standard rule to apply a lacing abdominal support to be worn for months. But it was ineffectual.

The importance of including the peritoneum within the sutures was early shown by Sir Spencer Wells, who advised the approximation of the divided edges of the wound with the utmost care.

During the past eight years he had employed exclusively the buried tendon suture in closure of abdominal wounds, except for a few months when he could not get it. For more than ten years previous to this he had used the buried animal suture in a great variety of wounds, and was led to its adoption in laparotomy because of its exceptional value in reinforcing the weakened structures, especially as demonstrated in operations for the cure of hernia. His method from the first had been essentially the same.

The peritoneum was closed separately. This might be effected in a variety of ways. For ease and rapidity, if for no other reason, the continuous suture was to be preferred. He usually employed the double continuous tendon suture (kangaroo tendon), which was easily and rapidly taken by the use of a needle with the eye near the point, and which, by rethreading with the opposite end, permitted the introduction of the suture from either side through the same puncture. The result was an even, continuous, and close apposition of the serous surfaces of the peritoneum, retained at rest without undue constriction. A fine tendon was used. When one of the recti had been incised, it was better to rejoin the muscles by a row of sutures. This finished, he considered the accurate coaptation of the thick investing fascia (linea alba) of the first importance. This was preferably effected by a line of sutures taken in a similar manner to the one closing the peritoneum. The more or less thick layer of fatty tissue was preferably brought into apposition by one or two light lines of running sutures. Care was taken that the needle reënter exactly opposite the point of previous entrance, at right angle to the line of incision, so as to secure perfect coaptation. It was called by him the parallel suture. The suture was buried. A layer of collodion, reënforced with a few fibres of cotton, applied to the well-dried skin, completed the dressing. If the operation had been conducted with aseptic care the wound must remain aseptic. In three hundred laparotomies, where a complete closure of its wound had been thus effected, he recalled but two cases of ventral hernia.

Undoubtedly, one of the most common causes of hernia was the routine use of drainage-tubes, by which a portion of the wound was necessarily kept open. He had used drainage-tubes in scarcely more than three per cent. A second and common cause of ventral hernia was imperfect coaptation of the wound edges by the interrupted suture, even when used with the utmost care. The suture itself, aseptic, aseptically buried, in aseptic wounds, marked one of the greatest advances in modern surgery. In over six hundred cases of wounds thus treated in his hospital the result showed less than two per cent. of suppurative wounds.

Dr. Schooler, of Des Moines, Ia., found interposition of peritoneum or fat between the united parts a chief cause of hernia.

Dr. Cordier, of Kansas City, passed one suture through all the tissues, and thought it could be done so as to secure as nearly as it was possible to do it coaptation of peritoneum to peritoneum, fascia to fascia, etc. The skin was retracted, and the needle passed in, sloping toward the mesial line.

The Propriety of Operative Measures in Pelvic Peritonitis.—Dr. Lewis Schooler, of Des Moines, Ia., read a paper with this title. On the one side were arrayed conservatives, with conservatism carried to timidity. On the other were the reckless and amateur operators, who occasionally might do good, but more frequently harm resulted.

Cases of pelvic peritonitis differed in their effects but little from general peritonitis save in degree and the liability to form abscesses. No cases were idiopathic. When moderate in degree, they recovered spontaneously or with the simplest treatment. The effused lymph might become organized, and after subsidence of inflammation important organs might be hindered in function. Repeated at-

tacks increased the difficulties. In the latter all would agree as to importance of operating. But it was in the acute cases that the skill of the diagnostician and therapeutist was put to the crucial test. When the tubes contained pus or the ovaries were diseased, he would remove them. Intra-uterine treatment in pyosalpinx had not been successful in his hands.

The conclusions of the author were, that in acute cases operate as soon as it becomes evident other measures would fail. In chronic cases there were two periods when operation was justifiable: First, when life was endangered during a recurrence; second, after subsidence of an acute exacerbation. The latter was regarded as the preferable period, but it could not always be secured.

The Essentials of Success in Vaginal Hysterectomy.—Dr. Henry T. Byford, of Chicago, read the paper. The author maintains that vaginal hysterectomy is an operation attended with little danger, and that the present mortality is caused mostly by: 1, operating upon unsuitable cases; 2, imperfection in the technique; 3, mistakes in the after-treatment. He summarizes as follows: 1. Operate only upon cases in which we can operate in healthy tissue. 2. Use the method and manœuvres adapted to each individual case, not adhering rigidly to any one for all cases. 3. Ligature enables to do a more complete operation than forceps, but forceps should be used when ligatures cannot be applied with accuracy. 4. When possible, place omentum between the intestines and the stumps. 5. Draw the ligatured stumps together and attach the peritoneal edges either to the vaginal edges or to each other. 6. Pack iodoform between the blades of the forceps, but do not allow the packing to project upward between the intestines. 7. Leave the packing for four days, as a rule. 8. Begin douches about eight hours after the packing has been removed, and use a rectum-tube the first time. 9. Keep the patient on the back for forty-eight hours. He reports thirty-seven cases, with one death, or a mortality of 2.7 per cent.

Surgical Treatment of Uterine Flexions.—Dr. M. B. Ward, of Topeka, read a brief paper, saying it was his desire to consider briefly the propriety of doing an abdominal section in suitable cases for retro-displacements of the uterus. It was unnecessary to preface his remarks with the statement that he who dared recommend such radical measures for an ailment of so insignificant a character was certain to be severely criticised. In his experience it had been extremely difficult, and usually impossible, to afford permanent relief in cases of chronic retroflexion by methods usually recommended. The larger number gave a history of long suffering, many attacks of pelvic peritonitis, which indicated that serious complications must be overcome before the uterus could be brought forward. It was this class of cases which the paper considered. His custom was to say to these patients that the local treatment would give comfort, and if they could exercise due patience they might be permanently relieved. He always informed them of the possibility of failure. The next plan recommended was to do abdominal section, break up adhesions, remove the appendages, if diseased, bring the uterus forward—all of which could be done quickly, safely, and effect permanent recovery. If there were only suspicion of ovarian disease, leave these organs, if the woman desired children. But from a large experience he could say that in nearly all cases of chronic retro-displacement of the uterus the appendages were seriously diseased.

(To be continued.)

Boric Acid, in daily dose of fifty to seventy-five centigrammes after a purgative dose of castor-oil containing five or six drops of turpentine, has been found by Tortchinsky to diminish diarrhœa, tympanites, and fever in typhoid.

Lead Colic has been treated with antipyrin in daily quantity of one drachm, which is considered by Devic and Chatin better treatment than by any other drug excepting belladonna.

Therapeutic Hints.

In Morphine Poisoning Dr. Daily stretches the sphincter ani with the bivalve speculum as often as respiration flags, and regards it as a plan well worth following.

In Bad Cold gelsemium arrests profuse nasal secretions, quiets headache and neuralgia, subdues cough and pain, favors a re-establishment of the secretions, through its influence upon the skin, kidneys, and gastro-intestinal tract. It reduces temperature and pulse-rate, promotes sleep, and creates a feeling of comfort and well-being without in any way approaching narcosis or destroying the oxygen-carrying capacity of the blood-corpuscles. Ten drops of a reliable fluid extract are dissolved in three ounces of water, and of this a teaspoonful is given every ten or fifteen minutes the first hour, then at less frequent intervals.—Aulde.

Trigeminal Neuralgia.—Dusquenal's crystallized aconitine, $\frac{1}{200}$ grain, gradually increased until numbness is felt all over the body, with chilliness and in some cases even nausea.

Red Iodide of Mercury, in doses increased from one-twentieth to one-sixth of a grain, and iodide of potassium, in twenty to forty-five grain dose after each meal, continued for two to three months, should be given, in addition to aconitine in tic-douloureux, even in the absence of syphilitic history.—Sequin.

Iodide of Potassium, when given in large dose, should be largely diluted. Delavan recommends essence of pepsin and milk.

Indian Hemp, in ten minim dose of the tincture three times daily, is almost a specific in insanity in women due to mental worry or moral shock, and is also of great value in mania and melancholia.—Suckling.

Gall-stone Colic is treated by Thudichum with morphine subcutaneously and large quantities of very dilute lemonade. If collapse threatens, chloroform anæsthesia is recommended.

Caffeine acts directly on the nervous system in vaso-motor heart troubles, and in moderate dose stimulates the heart muscle. Acting upon the cardiac innervation, it provokes dilatation of the vessels. With this drug muscular and nervous troubles of the heart can be combated which previously resisted all treatment. Beginning with daily dose of a quarter to half a gramme, it can be gradually increased until two or three grams, are taken in the twenty-four hours. It is best given subcutaneously, combined with an equal quantity of benzoate of soda.—Ferrara.

A New Tænifuge, proposed by Dr. Duhourcau, is the following combination in capsules:

Extract of male fern	1.20 gm.
Chloroform	3.60 gm.
Castor-oil	3.60 gm.
Croton-oil	gtt. ss.

To be divided into twelve doses.

Mild Eczemas and acne rosacea:

Benzoin	3 per cent.
Soap in powder	97 per cent.

Freckles.—

Mercury bichloride	0.50 gm.
Camphor	0.60 gm.
Alcohol	7 c.c.
Subacetate of lead	2.5 c.c.
Sulphate of zinc	2 50 gm.
Distilled water	250 c.c.
Yellow of an egg.	

Wet the face and let it dry on.—*Journ. de Méd. de Paris.*

Light in the sick-room should be insisted upon excepting in a few eye affections and other conditions requiring a darkened chamber.

Prophylactic in Tonsillitis.—For use by those persons predisposed to the development of tonsillitis:

℞. Olei menth. pip. ..... ℥ viij.
Acid. carbolic (crystal.) .... ʒ j.
Spt vini. rectificat. ..... ʒ ij.

M. Sig.: Ten drops to be added to a cup of warm water, and this solution used as a gargle night and morning.

—*Med. Rev.*

Chloride of Gold and Sodium has never failed to give relief in nervous cases, ranging from epilepsy to simple nervous manifestations without apparent cause.—Green.

Earache, without indications for operative interference, may be relieved with

℞. Menthol,
Gum camphor ....āā gr. xx.
Liq. albolene ..... ʒ j.

Drop into ear several times daily.—Dunn.

Angina Pectoris.—Inhalation of chloroform, or a few drops of nitrite of amyl; $\frac{1}{100}$ grain of nitro-glycerine, internally; placing the feet in hot water, mustard to the precordial region; dry cup between the shoulders; hypodermic injections of morphine and atropine, administration of stimulants and anodynes.

Apoplexy.—Elevate the head and shoulders; if pulse is moderately strong and the brain congested, bleed from the arm freely, sixteen ounces or more; elaterine (one-sixth grain), or croton-oil, two drops in drachm of sweet oil or glycerine; cold to the head by means of an ice-bag.

Heat Stroke.—Remove clothing, sprinkle with water, cold cloths to the head, hot cloths to the feet, antipyrin, bleeding in robust subjects. After temperature is reduced give alcohol and diffusible stimulants, hypodermically if necessary.—*Med. and Surg. Rep.*

Ipecacuanha is a powerful agent in producing uterine contraction during the first and second stages of labor.—Drapes.

Gonorrhœa.—

℞. Salol..... ʒ j. to ʒ ij.
Oleoresin cubebæ..... ..... ʒ ij.
Balsam. copaibæ..... ʒ ij.
Pepsin... .... gr. xij.
M. Ft. caps. no. xij. S.: One, six times daily.

—Hare.

Chlorohydrosulphate of quinine dissolves in its own weight of water and is rapidly absorbed. It is hence suitable for hypodermatic use and appears more active than the sulphate.—Grimaux.

Sodium Tetraboricum Neutrale has been attended with more marked success in chronic suppuration of the middle ear than any agent which Heflebower has ever used. It seems to be antiseptic and astringent and is used in sterilized saturated solution as an injection.—*Cincinnati Lancet-Clinic*, January 14, 1893.

Acute Anæmia, such as caused by post-partum hemorrhage, etc., is treated by copious rectal injections containing one and a half teaspoonfuls of common salt to the quart of water.

Neuralgia.—

Ammon. brom.,
Sodii salicyl.....āā ʒ j.
Tinct. hyoscyam..... ..... ʒ ij.
Aq.....ad ʒ iv.

Teaspoonful every half hour till relieved, or four doses are taken.—Hightower.

Pertussis.—

℞. Hyd. peroxide (10 vols.)..... ʒ vj.
Glycerine... ..... ʒ iv.
Water ....ad ʒ iij.

Dose: Half a fluid ounce, in a wineglassful of water, five or six times a day.—Richardson.

Glycerine, four parts, to bismuth, one part, is the best way to keep the latter in solution—Taurence.

Peritonitis.—The best treatment is by the administration of large doses of saline cathartics (sulphate of magnesium, ʒ ij., every two hours until the bowels have been opened eight or ten times).—Keen.

Camphor given with acetanilid overcomes the depressing effects.—Cshesmiutzeff.

Incontinentia Urinæ, when due to slight disorders of genito-urinary or nervous systems, may be relieved by rhus aromatica, beginning with five to ten drops and increasing to fifteen or twenty, four times daily.

Adherent Placenta.—Injection of cold water by the rectum acts by reflex stimulation.—Newton.

Typhoid Fever.—I have found beta-naphthol to work so well that unless the stomach is very irritable, which is a contra-indication to its use, I invariably give it, and my results guarantee the statement that it is an agent par excellence in the rational treatment of typhoid fever.—Shimonek.

Asthma.—At onset of attack, paint nasal fossæ as far in as possible with one part by weight of cocaine hydrochlorate to twenty of water, or spray nose and pharynx for four or five minutes. This may cut short the attack.—Dieulafoy.

Exophthalmic Goitre.—

℞. Powd. ipecac .... gm. .335
Powd. digitalis..... gm. .02
Ex. of opium..... gm. .0025

For one pill. Four or six to be given every twenty-four hours.

Bromoform exerts almost a specific action in whooping cough. One to five drops are given to children three or four times daily. It is best given in a mixture with alcohol and glycerine. The drug should be clear and colorless.—*Western Med. Rep.*

Naphthol as a Vermifuge.—Dr. Dubois gave fifteen centigrammes three times daily to a girl on whom he had tried all the usual remedies without result, and succeeded in causing a discharge of thirty-four ascarides lumbricoides. —*Lyon Medical.*

Tornwaldt's Disease, or chronic inflammation of a pathologically formed cavity, and frequently mistaken for post-nasal adenoids, is best treated, according to Smith-Hozier, with applications of chromic acid on a probe.

Resorcin is recommended for gastric ulcer, five grains three times a day. It is antiseptic, hemostatic, and analgesic, enabling the stomach to tolerate food.

Acute Rhinitis.—For relief of urgent distress cocaine and tincture belladonna in from three to five per cent. solution applied on cotton.—Pierce.

Sulpho-Carbolate of Zinc is recommended by Sangree in typhoid as capable of rendering the mucous membrane and intestinal contents less suitable for the development of micro-organisms. It is of little use to employ small doses, and five grains are given by the author every three or four hours until the temperature falls.—*The Times and Register.*

Puerperal Eclampsia.—Veratrum viride (Norwood's tincture) in sedative doses every half hour or hour until the desired effect is produced has been my favorite remedy for more than thirty years.—Stephens.

Dyspepsia.—The following treatment is useful in cases of obstinate indigestion:

℞. Tincture of cascarilla, cinnamon, gentian, colombo, rhubarb ..... .āā ʒ ij.
Tincture of nux vomica..... ... ʒ j.

—Jules Simon.

Cold Baths have been successfully employed by Rivière in two cases of tetanus after chloral and opium had failed.

Thymol is a useful addition to carron oil in treatment of burns, from $\frac{1}{20}$ to $\frac{1}{10}$ per cent.

Cimicifuga.—Ten to thirty drops of the fluid extract after meals cures seminal emissions.—Reed.

Ulcer of Stomach.—To combat the nausea and vomiting, a pill containing extract of belladonna, gr. $\frac{1}{8}$, and silver nitrate, gr. $\frac{1}{2}$, may be used with advantage; the latter is said to exercise a curative influence on the ulcerated surface, and by being converted into an insoluble chloride, diminishes or neutralizes the hydrochloric acid present in the stomach.—Wolff.

To Cut Short Whooping-cough, paint the periglotteal region every two hours with a ten per cent. solution of resorcin.—Moncorro.

Dysentery.—Hot enemata of tannin and boric acid.

Scotch Douche has given Schüller better results in chronic joint trouble of rheumatic origin than any other form of hydrotherapy.

Salicylate of Bismuth has been found useful in infantile diarrhœa, and lactic acid in many other forms, even that of phthisis.—*Lancet.*

Hydrogen Peroxide has been proved experimentally to be a valuable antidote in hydrocyanic poisoning.—Kobert.

Ichthyol Carbolic Varnish which can be readily removed is made by the following formula:

℞. Ichthyol	25.	parts.
Carbolic acid	2.5	"
Starch	50.	"
Water	22.5	"

The first two are dissolved in water at a gentle heat and the starch added.

Cholera.—Chloral, by hypodermic injection, has been extolled. The following is a suitable formula:

℞. Chloral hydrat	ʒ iij.
Morphin. sulph	gr. j.
Atropin. sulph	gr. ¼.
Aquæ chloroformi,	
Aquæ	āā ʒ ss.

M. Sig.: Twenty minims, repeated in ten minutes, and subsequently pro re nata.

—Bartholow.

Tertiary Affections of the Penis must not be confounded with initial sore nor with chancroid, or when in urethra with gonorrhœa. Iodide of potassium is the indication.—Sternthal.

Pental, administered as an anæsthetic in from two to eight gramme doses, causes loss of consciousness lasting from half a minute to fifteen minutes. In incomplete narcosis tactile sensibility sometimes appears unaffected, though sensibility to pain is totally abolished.—Fedoroff.

Nocturnal Emissions.—

℞. Ext. aloes	gr. iij.
Ext. belladonnæ	gr. ij.
Ext. hyoscyami	gr. iv.
Pulv. camphoræ	gr. iv.

M. Ft. pilulæ No. xii. Sig.: One pill every night.

Creosote is no longer an innovation or a fad, but a drug which has come to stay as an antitubercular remedy. It is particularly valuable in the earlier stages of tuberculosis. Its administration must be in moderate doses for a prolonged period. It is a safe and reliable prophylactic in the condition that is usually described as pretubercular anæmia.—Stark.

Veratrum Viride is considered a safe drug and a sure remedy in scarlet fever, and it is thought that some cases may be aborted by its timely use.—Chambers.

Appendicitis, if Seen Early.—Absolute rest, fomentations, salines every half hour until four or six fluid stools are produced.—Jonas.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PARLIAMENTARY COMMITTEE ON DEATH CERTIFICATION—THE GENERAL MEDICAL COUNCIL—PRACTICE ABROAD—SMALL-POX—SCARLET FEVER—DEATHS OF MARCUS BECKT. SIMPSON, AND PROFESSOR PACCHIOTI—THE GENERAL MEDICAL COUNCIL—MEDICAL AID ASSOCIATIONS—COVERING—VISITORS OF EXAMINATIONS—THE CURRICULUM—THE NEXT PHARMACOPŒIA—SUSPENSION OF AMERICAN DENTAL DIPLOMAS—THE CLINICAL SOCIETY'S CLOSING MEETING—DEATH OF THE SECRETARY, DR. HADDEN—ROYAL CHARTER FOR NURSES—SIR WILLIAM JENNER'S WRITINGS.

London, May 27, 1893

Subjects of interest to the profession have not been wanting in Parliament of late. Among them is that of death certification, which is now being examined by a select committee of the House of Commons. Already this committee has had before it a number of witnesses, among whom were doctors, coroners, registrars, health officers, and, with the usual impartiality of such committees, a representative of unqualified practitioners, and especially of herbalists. The last-named seem fairly satisfied with the present system, though they would prefer it to be rather more lax. They evidently fear that any alteration will be in the opposite direction. Ordinarily, medical men are required to certify the deaths of their patients on a form provided by the Registrar-General, giving the date when last seen and the day and cause of death. This certificate passes to the Registrar of the district, who gives his certificate of registration to the person authorized to conduct the funeral. It is from these certificates, which are not paid for, that the Registrar-General's valuable statistics are framed. The profession, knowing the importance of such statistics, has always been willing to give its assistance, and may surely expect in return that certificates should be accepted from qualified practitioners only. It seems, however, that great irregularities in this respect have prevailed, and when no qualified practitioner has seen the case or been willing to certify, that registration has nevertheless been effected. Such cases ought to be inquired into by the coroners, but inquests are very unpopular and some of these functionaries, whose salaries do not depend on the number of their inquiries, have not been too anxious to increase them. In other ways, too, abuses have crept in—it is not usual to register stillbirths, a midwife's certificate is merely given to the undertaker. Moreover, great laxity has prevailed, with here and there a medical man who has signed blank forms and allowed his assistant to use them. Some, too, have done this for unqualified men and so "covered" them; but the Medical Council has decided that "covering" is "infamous in a professional respect," to use the words of the Act of Parliament, and will entail exclusion from the Register, so that this offence will probably cease. It seems to be generally admitted that registration of deaths should be made compulsory, that qualified men should be paid for certifying, and that all cases not certified by them should be subject to a coroner's inquest.

The session of the Medical Council opened on Tuesday, with the usual address of the President, giving a summary of the business to be transacted. A very full agenda was before the members, including important reports of the Education Committee, and the Examination Committee. The former is under discussion as I write; the former contained reports of the visitors of examinations, and was discussed on Thursday in reference to some defects pointed out in one of the examinations of the Dublin University, which the representative of that body assured the Council would at once be removed. Sir Philip Smyly took his seat as the successor of the late Dr. Macnamara, whose death I have previously mentioned, and to whom

the President paid a feeling tribute. He mentioned the action in which the College of Physicians had succeeded against the Council, and that the costs thereby incurred will be little short of one thousand pounds. Does it not seem deplorable that a thousand pounds sterling should be squandered in a legal contest which could not benefit the practitioners who have contributed the funds? And all the while the country swarms with quacks which the Council does not suppress. No one cared a farthing about the lawsuit undertaken except the College, which naturally fought for its privileges. No one doubted that its licentiates were fully qualified, and yet the Council refused to recognize the license as a double qualification, while it takes no thought or does next to nothing as to men with no qualification at all. On Wednesday and part of Thursday cases of discipline were undertaken. Three names were ordered to be removed from the Register. One name was restored. This leads me to remark that in all directions there seems to be a growing feeling that restoration is too easily obtained. Of course there are differences in the offences, and the greatest care ought to be exercised to prevent expulsion becoming too light a punishment. An interval might, perhaps, in each case be fixed before the expiration of which no application for restoration could be entertained.

Papers were laid before the Council on the subject of reciprocity in practice in various countries. France and Switzerland are the most exclusive, especially the latter. Great complaints have been made that English physicians cannot attend their patients in various health-resorts. The remedy is to send our patients to other equally beneficial localities where more liberal views prevail. When Switzerland has diverted the stream from which much of her prosperity comes she will have time enough to repent of her folly.

Small-pox continues to spread. There were 537 cases in the Metropolitan Asylums Board's hospitals on the 20th instant, and fresh outbreaks are reported from various towns. Scarlet fever also continues to prevail both in London and the country.

Surgery has lost a distinguished exponent, and University College a model and beloved teacher, in Mr. Marcus Beck, who died on Sunday last and was buried on Thursday in a burying-ground of the Society of Friends. He was the subject of diabetes, but never suffered that to interfere with his devotion to his work. An attack of influenza hastened the end, and he died of diabetic coma at the early age of forty-nine. His name must be well known to your readers as the editor of recent editions of Erichsen's "Surgery."

A man of somewhat similar sturdy character, but whose lot was cast in a country town, was Thomas Simpson, of Coggeshall, where he spent some forty years of unpretending, earnest labor. I knew him well, and like his other friends, held him in high esteem. He loved literature, science, and his profession; was intellectual, benevolent, pious, and well cultivated. His death will leave a great blank in the place that had known his worth so long.

Another friend of mine, although an Italian, was well known to many in London, Professor Pacchiotti, of Turin. The last time I saw him was at my own clinic, where he came with all his usual professional ardor. Italy has lost in him a noble representative. She has indeed been severely visited of late, for within a few days she has lost him and Cantani, and also her world-renowned adopted son, James Moleschott.

LONDON, June 3, 1893.

MEDICAL aid associations, as they are called, have been formed in various towns, to apply the co-operative principle to medical attendance. This is an advance on the friendly societies or clubs which have long been recognized as useful institutions. Much opposition has been roused by these newly-formed associations. It has been urged that they are in reality gigantic co-operative societies dealing in unqualified medical practice protected by the "covering" of a qualified man. Various other charges have been made, such as that of "sweating" the doctors, making them utterly dependent, and touting for practice in a disgraceful manner. No one can doubt that a great abuse has sprung up, but who is to blame? So rapidly has the abuse spread that the General Medical Council has been compelled by the outcry raised to look into the matter. The Council accordingly appointed a committee to investigate and report, and the present session has been eagerly looked forward to in the expectation of an important resolution being adopted. But the eager spirits who had not gauged the *vis inertiæ* of the Council have been doomed to disappointment. The report of the committee was indeed brought up on May 26th, and so feeble a document it proved to be that it might almost have been mistaken for the offspring of the Council itself. But not quite, and so the Council proceeded to its usual work—talk and empty resolutions of platitudes. A day was consumed over this, which, at the rate of about a guinea per minute (the amount the Council meetings have been calculated to cost the profession), will be enough perhaps to deter any further appeal to its authority by the enthusiasts who expect the dignity of the profession to be maintained by its action. That dignity is upheld by the gentlemen who collect their fees for attending these meetings. The committee had proposed to stigmatize certain actions as "reprehensible," but objection was taken to this on the ground that the Act of Parliament used the term "infamous in a professional respect," and that therefore the Council was not empowered to use any other term. This objection was not taken with a view to the use of the term infamous, but to get rid of the condemnatory resolution, as it was well understood the Council would not display the courage of its convictions. No doubt it is a severe punishment to remove a name from the Register, but when lawyers are "struck off the roll" we hear no feeble sentimentalism of that kind, and so the sister profession manages to keep up its reputation at a high social level. The Council did agree to declare that the offence of "covering" was committed by medical officers of these associations keeping unqualified assistants, and further, that the "report of the committee with reference to certain evils which it describes could not fail to be instructive to the executive committees and medical officers concerned," and copies are to be forwarded to these persons. Those who know the history of the Council will take this as the usual *laissez faire* policy. Possibly one or two of the bodies may take it as a warning to mend their ways. If not, the Council may look for further disturbance of its slumbers.

The report of the visitors of examinations was the next most important subject before the Council, and the attention of several qualifying bodies was called to certain defects in their methods of examination, which will no doubt be speedily removed. The curriculum of five years was considered to be evaded by those bodies which admit study in science previous to registration to count. This point may cause the Council a difficulty before which it will relapse into its well-loved inaction; for the regulations of the Scottish Universities have been settled by commissioners under Act of Parliament.

The Pharmacopœia Committee was authorized to take steps to make the next edition of the work, which may appear two or three years hence, more acceptable to India and the colonies by including their more important natural remedies. Will this prove a step toward an international codex?

The Council determined to suspend for a time the registration of American diplomas in dentistry, as it appeared they were granted after a less curriculum than British dental diplomas. The names of those already on the foreign dentists' list will of course be retained.

The annual meeting closing the session of the Clinical Society was held on the 26th ult, under sad circumstances. The chair on the right hand of the President, filled at the last meeting as usual by the senior secretary, Dr. W. B. Hadden, was vacant. Within the few days that had in-

tervened since that last meeting, Dr. Hadden, then in full health and enjoying his work, was struck down by pneumonia of septic origin. To some present the first intimation of his untimely decease came at the meeting, for he had only died that day, and he was to have read a paper at this very meeting. The President referred in touching terms to this sudden event, and bore testimony to the excellence of Dr. Hadden's work as a scientific investigator, to the energy he evinced in all he undertook, and to the courtesy and zeal with which for the past two years he had devoted himself to the duties of secretary of the Society. The condolences of the Society were voted to the parents of Dr. Hadden, on their great loss. He was senior assistant physician to St. Thomas's Hospital, and also on the staff of the Children's Hospital, and only thirty-seven years of age. He would have been re elected secretary at this meeting with the other officers whose names were on the list, which was duly passed.

The clinical business proper was also duly gone through. This consisted of a case of ulcerative (or, according to another's view, membranous) colitis, treated successfully by inguinal colotomy, and subsequent irrigation with boric solution of the surface between the anus and the artificial opening; two cases of chronic albuminuria of long standing, twenty-five and forty-three years, respectively; fatal asphyxia following self-administration of nitrous oxide.

The Royal British Nurses Association has obtained a charter of incorporation.

Sir William Jenner, in his retirement, has arranged some of his scattered lectures and communications for publication in book form. His valuable studies on fevers and diphtheria will appear in the first volume, now in the press.

I hope he will do justice to the late Dr. A. P. Stewart's work in discriminating typhus and typhoid.

THE USE OF NITRATE OF SILVER IN SOLUTION IN GASTRIC ULCER.

To the Editor of the Medical Record.

Sir: The admirable article by Dr. I. Boas, of Berlin, in the Record of June 17th, calls the attention of the profession to the use of nitrate of silver in gastric ulcer, and especially to its use in solution. I can add my testimony to its efficacy, used in this way, but with a modification which permits the administration of larger doses when advisable, without any unpleasant effects.

As long ago as 1887, I began using the nitrate of silver in solution in chronic gastric catarrh, and in cases of obscure stomach disease, where great pain on pressure over a small area and distress soon after eating led me to suspect the presence of an ulcer; but where some of the more characteristic symptoms were wanting to establish a certain diagnosis, my plan of giving the silver in solution has been as follows: At first the patient is directed to drink eight ounces of warm water, and after half an hour, another glass of water in which one grain or more of the nitrate of silver has been dissolved is taken, this to be followed in fifteen minutes by a cup of water containing a pinch of chloride of sodium; this last procedure is, of course, not necessary when small doses are given; but it enables us to administer large doses, well diluted of course, when desirable, and as in these cases it is the local effect of the remedy we desire, it is just as well to neutralize the drug, in part at least, before its absorption. The history of the first case in which I used the remedy in this way is as follows:

Mrs. B——, a widow about fifty years of age, consulted me in October, 1887, and gave a history of long suffering from inability to digest food. She often vomited and suffered great pain in the epigastrium, the pain was circumscribed, was transmitted through to the back, and was much intensified upon pressure; there was no history of vomiting of blood, nor had blood been observed in the stools. There was constipation and great emaciation, and all kinds of food were imperfectly digested. I directed the patient to take in eight ounces of warm water, one grain of nitrate of silver, after previously taking the warm water as above noted, and this latter to be followed in fifteen minutes with a cup of water containing a few grains of salt. This procedure was repeated once a day for a few days only, and after that every second or third day for a while. The result was excellent and the patient very much relieved, she could digest carefully selected food, and gained a considerable degree of health. A year later there was a slight relapse, but this yielded to treatment, and the patient remained up to about a year ago, when I last saw her, much improved. I have since that time made occasional use of the nitrate of silver in solution, in cases where a rather chronic ulcer of the stomach has been suspected, when great emaciation and a cachectic appearance had led me to fear malignant disease. In such cases I believe it efficient. In more recent cases, where the symptoms have not been so severe, I have not found it to be generally superior to the use of small doses of the silver salt in pill form. These, however, I generally give on an empty stomach, and let the patient drink a little water, and rest for a time after taking them, no food to be taken for an hour. The question arises how the silver acts, and whether it is not speedily neutralized by the hydrochloric acid it meets, or may meet, in the stomach. Without going fully into the subject it is fair, I think, to assume that when taken fasting, and not within an hour of meal-times, it will act efficiently without chemical change. The method of giving from one-half grain to two, or even five grains in solution in from two to twelve ounces of water, seems to promise the best results, when its local action is desired, and its neutralization by the administration of the chloride of sodium permits the administration of large doses when necessary.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 24, 1893.

	Cases.	Deaths.
Typhus fever	5	3
Typhoid fever	20	6
Scarlet fever	97	16
Cerebro-spinal meningitis	8	10
Measles	224	14
Diphtheria	115	34
Small-pox	8	3
Cholera	0	0
Varciella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

The Prognosis of Pott's Disease must be considered under four headings: as to life, as to the complications, abscess and paraplegia, and as to the deformity. As to life: Although Pott's disease is a most prolonged and serious disease, the prognosis as to life is remarkably good; only about eight per cent. die of those receiving proper nursing and treatment. In these few the cause of death is invariably due to tubercular meningitis or general tuberculosis in which the meningeal symptoms play a most prominent part. The abscess of Pott's disease, if uninterfered with, rarely causes trouble. If the area of bone disease be efficiently immobilized, the abscess, in about half the cases, disappears without coming to an opening. In the remaining cases it bursts, discharges for a longer or shorter time, and closes. Treated by aspiration and the injection of the iodoform and glycerine mixture, the cure is hastened in a certain number of cases; in other instances nothing seems to be gained by the procedure, and in a few cases a true sup-

purative process is grafted on to the tubercular inflammation. Treatment by incision, scraping, and drainage in pure tubercular abscesses, untainted with septic infection, rarely aids the cure in the slightest, and greatly adds to the risk from general tubercular infection and from septicæmia. The paraplegia, which occurs in a considerable number of cases of upper dorsal Pott's disease, though rarely in cervical and lumbar disease, need cause little anxiety. Rarely is the paralysis due to pressure of bone, or to tuberculosis of the cord itself. The acuteness of the angle of deformity bears no relation to the paralysis, since we not infrequently see the paralysis pass off while the deformity continues to increase. Cases of paraplegia from bony encroachment invariably terminate fatally, unless the pressure be relieved by operative interference. Cases in which the tubercular inflammation has invaded the cord itself always die. In the vast majority of cases the paralysis is due to a peripachymeningitis, and the prognosis is good, provided the patient can be kept recumbent and the area of disease immobilized. Relapse may occur, but ultimately the paralysis is fully recovered from. The prognosis as to deformity and function depends upon the location of the disease and the amount of consolidation present when treatment is commenced. If consolidation is not already present, deformity can be fully corrected in the cervical spine, and normal function regained. In the dorso-lumbar region—tenth dorsal to third lumbar inclusive—the deformity can be somewhat reduced, and at times in young children wholly effaced. Some rigidity usually remains, but in the very young, if the deformity is fully corrected, full motion may be regained. Disease in the upper dorsal region invariably results in some deformity before a positive diagnosis is made, and this, as a rule, increases somewhat during treatment. Disease at the fourth and fifth lumbar vertebræ must be treated with complete recumbency for a long period if deformity would be avoided: when, however, deformity has occurred, it cannot, as a rule, be remedied. The prognosis as to deformity, wherever the disease is located, depends very much upon the time of making the diagnosis, and the ability to carry out an ideal line of treatment. If the disease can be diagnosticated before deformity has occurred, and if proper treatment can be persistently carried out, deformity may be prevented in all cases and the duration of the disease greatly lessened.—John Ridlon, M.D., in the Chicago *Medical Recorder*.

Berlin boasts of its four lady doctors already—whether the profession will be further increased through feminine assailants remains to be seen; but if Herr Baumbach's motion is carried, which he brought forward lately with much eloquence in the Reichstag, asking that women be permitted to present themselves for the Staat's Examen—with a view to practising medicine—if this is finally carried we can only imagine that the existing female practitioners will have their numbers largely augmented in Berlin as in other German towns.—*The Hospital.*

Grafting a Dog's Skull.—From Paris comes an account of an operation performed by M. Ricard, on a woman of forty five, who had suffered from a tumor in the frontal bone. A portion of the bone had to be removed in order to get rid of the tumor, and as the brain was laid bare in consequence, cerebral hernia ensued. M. Ricard had the idea of removing a piece of living bone from a dog's skull, and cutting it exactly to fit into the void in the woman's forehead. He took antiseptic precautions—the grafted piece was knit with the frontal bone, into which it was inserted, and the patient made a good recovery. Dr. Polaillon has presented a report on the case to the Académie de Médecine, and speaks of the operation as the first successful one of the kind ever performed. The operation is in the same line with others done in this city.

Salol combined with phenacetine is especially useful in influenza and rheumatism.—Shoemaker.

BOOKS RECEIVED.

Brain Surgery. By M. Allen Sarr, M.D., Ph.D., Professor of Diseases of the Mind and Nervous System, College of Physicians and Surgeons, Medical Department of Columbia College, New York; President of the New York Neurological Society: Consulting Neurologist to the Presbyterian, Orthopædic, and Babies' Hospitals. With fifty-nine Illustrations. Octavo, 308 pages, extra muslin, price, $3. New York: William Wood & Company.

Human Monstrosities. By B. C. Hirst, M.D., and G. A. Piersol, M.D. Part IV. Pages 151–220. Plates xxv.–xxxix. Lea Brothers & Co., Philadelphia, Pa.

Clinical Lectures on Abdominal Hernia. By W. H. Bennett. 8vo, 225 pages. Longmans, Green & Co., New York. Price, $2.50.

Transactions of the American Pediatric Society. Fourth Session, 1892. Vol. IV. 8vo. 277 pages.

THERAPEUTICAL SUPERSTITION.[1]

BY GEORGE T. WELCH, M.D.,

PASSAIC, N. J.

RECENT researches into obsolete medical works have convinced me that an old scientific book is not more valuable in any other way than it is in what it represents as a landmark of the attainment of thought and speculation up to the very hour that it issued from the press. Truth changes its aspect; what we have thought was an eternal principle was some issue caught motionless at a turn of the tide. When we have believed penetration could go no farther, some fresher genius has taken the trail, and disappeared, after shining for a moment upon a farther upland.

The Romans erected arches to victory and columns in remote provinces to mark their ever-widening boundaries. Beyond many of these flowed the human tide, rising in continued swells of grandeur to this hour; but some of them are to be found by chance travellers in deserts, and some have mouldered quite away in vast solitudes. And just as these ancient and daring conquerors marked their latest triumphs with monumental shafts and sculpture, on which were graven battles and the names of heroes, so in our books the great teachers and historians of our art have celebrated the achievements of the profession and recorded the long roll of illustrious physicians. Some of these books, even so far back as the famous one of Hippocrates, have been guides to prosperity, while others have been shunned as pointing the way to haunts of superstition and morasses of the human mind.

We smile superiorly when we look at some of them and perceive how very little had been wrested from ignorance and credulity while the book itself is so pretentious. And yet every recruit, every appliance of skill, wisdom of the fathers, resource of the sons, drift of theories, fragments of tradition, charms even, and necromancy, all that was believed and all that was hoped, were brought together under the standard that was borne thus far into the wilderness—the Scythia that besets us with difficulties and every morning presents a farther horizon. And the latest book has brought all up to date, and with an unremitting courage the author has placed another shaft to victory, which we begin already to leave a day's journey behind us.

Nothing is established, nothing is sure! is a hopeless cry sometimes heard. But we, like the Roman, leave a regent in every conquered province, where, if the court shifts and the elements revolve, we still govern upon principles that defend us. Nor have we any reason to feel the superiority of any other profession above our own, when we reflect that all alike are humbled before vast problems, and either feel their way with caution, or are rebuked by the judgment of posterity. The austere creeds of the theologian are constantly crumbling. That which must be defended is no longer impregnable. Divinity is breaking into a thousand sects. The ameliorating, humanizing principle is abroad. Some of the weaker minds, not daring to try the issue, are for leading their flocks back into the old paths. They spurn their natural leaders and condemn them as outlaws, while with vestments and rituals they seek to lull the human mind. They had as well seek to bind the floods with cassock bands, and seal the caves of the winds with threats and excommunication.

Should we turn to statesmanship, we find armed neutrality. The invention is sterile that dares not dare. And yet empires are but maps of an hour. Slight incursions change boundaries. In law we approach the exasperation of politics. It is always changing and never satisfactory. It is a net that draws hard upon the petty criminal, but bursts when a corporation is entangled. Descartes found a whole library in the human body, but your lawyer, confronted with a perplexing cause, goes to a myriad of books to find his clues.

We fret and repine because every physician that prescribes for an ailment is not a trained scholar in his profession, and we fulminate about it so much that, mistaking our conscientious care for an admission, the other professions smirk and grimace, but the egotist with the longest purse goes to the senate, and the ruffian with the greatest saloon interest becomes the lawmaker for a State. In the cabinet there is vacillation, in the senate great measures stagnate, in the legislature partisanship predominates. Smug hirelings climb the pulpit—"the hungry sheep look up and are not fed."

In the natural sciences the savants are still classifying. The astronomer is not sure that his burned-out suns may not be stars about to germinate.

In the face of all this dilettanteism, what reason have we to stand at bay! We have gone far and have established much. No one will deny the potency of Jenner's vaccine, or Lister's antiseptic methods, and all that goes under the comprehensive title of hygiene. The study of preventable causes of disease is raising the standard of medicine, and just as physicians recognize that their mission is a wider one than the mere administering of drugs to cure the ill will they exalt their profession, and become an established power in government. For if we exclude from the human family all the preventable diseases—including those produced by worry and mental strain, by physical strain, the excesses of the passions, by alcohol, tobacco, narcotics, unwholesome foods, impure air, by occupation, sloth and idleness, late hours and broken sleep, errors of dress, imitation and moral contagion, automatic diseases and hypochondriasis—all of which are evils that may be avoided—how small a percentage would be left for the doubtful compounds of the pharmacopœia! "If intermarriage of diseases were considered in the same light as intermarriage of poverty, hereditary transmission of disease, the basis of so much misery in the world, would be at an end in three or four generations" (Richardson).

There will come a day early in the next century when a Secretary of Health will be as necessary a member of the Cabinet as he who holds the portfolio of Law or Agriculture. That this has not been so long ago, in all countries, is not so much the fault of a progressive profession as it is of a vicious education in therapeutics. For however man may deteriorate his health, however long he may have put at defiance every law of nature, he demands an instant cure. He may scoff at miracles elsewhere in the natural world, but he confidently expects one at the hands of his physician at any hour, let the disease be what it may. And the physicians are few who boldly stem this senseless tide. The majority yield to it: go with the current, pander the superstition. Vainly they

[1] President's Address, delivered at the One Hundred and Twenty-seventh Annual Meeting of the New Jersey Medical Society, June 27, 1893, held at Asbury Park, N. J.

offer this or that panacea, and painfully reminded by past experience that the discouraged patient may suddenly leave and go to the coast of some other Bohemia, they make a dizzy change from drug to drug, but the demon of disease looks out and leers at them. He will not be propitiated, or poisoned in his keep.

To have perfection in the child, says Holmes, we must begin with his grandfather, and in morals no man expects that a clergyman hastily called in, will, by some hocus pocus, make saint of one who, long a sinner, has at length committed some atrocious crime. The mills of God grind slowly — and human laws are inexorable too. The transgressor finds to his cost that he must endure many fluctuations of hope, many fines and penalties, for the delays of the law are proverbial. There are, it is true, many ephemeral laws, such as have scourged us at Trenton, since booted and spurred the jockeys have ridden the State till the galled jade winces; but the Supreme Court has remedied these right speedily; and so there are ephemeral diseases that Nature will right, and which must succumb of themselves.

And without cavil it is in the self-limited diseases that the incessant therapeutist has won his most signal triumphs. Like the fox in the fable, he has a thousand tricks by which he can baffle the acute assaults of la grippe, pleuritis, bronchitis, asthma, pertussis, endocarditis, dysentery, chorea, rubeola, dengue, and acute rheumatism—for these are diseases whose tendency is to recovery. But he is less brilliant when pitted against croupous pneumonia, laryngitis, croup, œdema of the glottis, angina pectoris, acute gastritis, cholera, peritonitis, hepatitis, apoplexy, meningitis, tetanus, typhus fever, yellow fever, small-pox, and diphtheria, for these are dangerous diseases.

He is restless and feels the prescience of defeat, though still dosing the adversary largely, when it comes to a conflict with the chronic diseases, such as general paralysis, paralysis agitans, phthisis, epilepsy, progressive locomotor ataxia, and Bright's disease. And he is obliged to sit down to a regular siege before all the diseases which, though acute at first, have become chronic in spite of all his drugs. For disasters like these he has numberless excuses, as that the patient was already debilitated, he contracted a cold, there were complications, an unmanageable diathesis was awakened! And then come the incurable diseases, such as gastric ulcer, carcinoma, cirrhosis of the liver, acute atrophy of the liver, and chronic diffuse nephritis. In the presence of these, the most inveterate dispenser of drugs, seeing the death-warrant, patent to all eyes but his who must suffer and endure, must stand humbled amid his pots and vials. He must, else, pour his libations in vain.

And is it not singular that drugs should be esteemed so powerful in the acute, self-limited diseases, and yet in the chronic types, where the opportunities for their potency is so prolonged, they should fail so signally!

As knowledge accumulates, this or that drug of the fathers, which was wont to be so irresistible in fever, in imposthumes, or what not, is laid upon the shelf. We now know and can demonstrate that it was utterly useless; and yet the patient often got well! Every physician who has been spared to a great age can look back upon pharmacies ever changing. On the Ariel-wings of memory he can glance into a thousand sick-rooms, and sniff the odors of drugs no longer known. They had their day and the fashion changed.

Men couldn't be soundly cured without calomel once, and veratrum viride was a later triumph. Cod liver oil was once the Utopian remedy for phthisis. And it is astonishing how an enthusiastic therapeutist can always find the improvement his horoscope has forecast. But in fact he is only the antipode of the specialist, who is never known to examine a subject who has not something wrong in his line of business. Dr. Wood, in the fourth edition of his "Practice of Medicine," 1855, gives what may be taken as the average view of the physicians of the day, in regard to the benefits of cod-liver oil in phthisis, for the old professor was never rash; but we shall find that his opinion was tinted by the prevailing sentiment. "It does not act as a specific," says he, "and is wholly incapable of producing, by any direct influence of its own, the removal of the deposited tuberculous matter. But it invigorates digestion, improves the character of the blood, and by a peculiar power modifies the nutritive process, so as to obviate in a greater or less degree the tendency to the deposition of tuberculous matter."

Now, I question whether it is the experience of any scrutinizing physician to-day that cod-liver oil invigorates digestion; if it did, it would be the remedy par excellence, for the natural history of the disease in question shows that the fatal result is at length brought about by the gradual undermining and impairment of the appetite and digestion, which, once destroyed, the whole fabric collapses. And of all animal substances given to a man, we shall find the ingestion of fats furnishes the most serious problem for the functional processes of the stomach and intestines. Now, long before J. Hughes Bennett voiced the popular impression that the origin of phthisis is due to defective fat digestion it was the unwritten law that strumous indigestion and the indigestion of fats were synonymous terms. And not even a knight-errant in medicine would now deny the connection of the indigestion of fats with the strumous diathesis. The healthy stomach that has not been appalled by sweets and sours, and fats and leans, hot fluids and ices, dry wines and sparkling, and all the menu of a modern dinner of state, may also digest cod-liver oil mixed with ordinary food; but, if more than a moderate amount is added, the digestion becomes deranged with all the hideous symptoms dyspeptics are so fond of confiding. What then of the stomach already far gone? Would you load a staggering porter with a few pounds more, every time he faltered past you, on the theory that it would improve his strength?

When I was a student in the University and hospitals of Philadelphia, solutions and syrups of bromide of potassium were the popular tipple for all sorts of diseases, and quinine became the universal panacea for the laity just as it was losing ground with the profession; but the coal-tar derivatives are pushing all others to the wall. The chemists would seem to have gone mad in their laboratories, and to have applied the match to a new system of fireworks, so bewildering are their nimble coruscations of saccharine, pyrolin, hydroxylamine, methacetin, thallin, and exalgin. But the sparks die out as suddenly as they astonished, and many of them are already forgotten.

When it comes to this, that most of the self-limited diseases will get well without drugs; that some of the acute diseases with unfavorable complications got well in the previous generation, and in the centuries gone, under the prescription of drugs now known either to have been inert, or misapplied; and when we recognize the fact that within five years the medical journals teemed with the encomiums of new drugs which are already superseded by others which, in their turn, are getting a little *passé*, the confused physician may well exclaim with the dazed political vivant, "Where am I at!" He might feel his faith seriously shaken when he recalled how sadly he had been duped by the old pharmacologists, and the organic chemists of the hour.

When we regard the fact that the earth everywhere, unless depopulated by merciless greed, is teeming with animal life in the highest state of perfection, which has been evolved from parent to parent through unmeasured æons, and that in his savage state man himself, until corrupted by his civilized congener, has been found to be of fascinating feature and vigor, we must admit that drugs have not been necessary to perpetuate and strengthen the races. And when we reflect that, though the complex forces of civilization have induced a variety of diseases, many of them are preventable, and many of them self-limited, and therefore to be got rid of without drugs, and that the chronic forms of disease resist drugs, and that upon the whole the bills of mortality have not been lessened by them, we must conclude that our profession has

given altogether too much prominence to the apothecary's art, and raised expectations in the minds of the ill which cannot be realized. Further, it has set upon them hordes of charlatans, which, like evil birds, fatten upon human miseries.

It is time that we should reform ourselves and convince the public that there are higher potencies than the therapeutical superstitions that we have dealt out to them. We detest and execrate the priesthood for driving a shrewd trade with the bones, and relics, and other useless lumber of the saints, but we have unconsciously set up a barter of a like kind, and need to have our temple scourged of the money changers too.

I am aware that it will be urged that the average physician of to-day is much more wary in the use of drugs, and that upon the whole smaller doses prevail, and greater discrimination is exercised. I have heard, too, that the world has grown better, wars less numerous, man more concerned in raising his neighbor than in raising himself upon his neighbor. But I note that the sentinels of old empires grimly regard each other across the borders, that Justice in the South is not only blindfolded, but has her hands tied willingly behind her back, that the saloon domineers our politics, that the shadow of the prison falls across the threshold of the temple. And I know that in 1889, there were imported into this country $13,186,290 worth of drugs used in medicine, and that the succeeding years have not shown a less amount. I know, too, that there has been no inverse ratio existing between pharmacists and physicians.

In an essay on this topic in 1889, I showed from the "Statistics of Commerce and Navigation of the United States, for the Year ending June 30th," the gross amount, in pounds, of the chief drugs used in practice, which were imported to that date. I have just received from the Secretary of the Treasury the volume containing the statistics of the importations for the year ending June 30, 1892, and I find the following startling items:

Quinia sulph.....	2,686,677 ozs.	Opium (nine per cent. morphia)..	587,121 lbs.
Cantharides.....	10,446 lbs.	Rhubarb.....	118,874 "
Balsam copaiba....	206,011 "	Salicine.....	5,152 "
Aloes.....	255,394 "	Morphia, and all salts thereof....	42,301 ozs.
Assafœtida.....	125,557 "	Calomel and other mercurial medicinal preparations	12,630 lbs.
Ipecac.....	38,329 "	Alkaloids and alkalies to the am't of	$827,230
Jalap.....	112,601 "		
Manna.....	49,335 "		
Ergot.....	125,148 "		
Cubebs.....	115,974 "		
Nux vomica.....	1,392,437 "		

Certainly, no one can complain that there will not be enough to go round. Every mail is turgid with the pleas of manufacturing druggists. Our daily papers and religious weeklies are insidiously padded with advertisements of cure-alls. Postal cards, like so many tormenting gadflies, are pestering the sixty odd thousand physicians of America with the information that this or that compound is the only safe remedy for lung, kidney, or brain diseases. And these drugs do not pass into innoxious desuetude—they are all used somewhere.

Whoever has had the curiosity to read the minor medical journals, that he might know what is going on in the under world, must have been struck with the therapeutic greed of the writers—practical fellows who go scrambling crab wise over pathology to seize proprietary mixtures which are labelled to cure all the ills under the evil planets. The quacks grown wary, having been beaten off the field by the tremendous reinforcements in the medical ranks, return to vend their wares to the physicians themselves.

I have searched a large number of the pamphlets and medical journals of all classes, during the past three months, so that I might note the therapeutical extremes in this quarter of the latest years of the closing century. Brown-Séquard and his disciples are patiently engaged in the injections of organic liquids He is not rejuvenating octogenarians, with spermatin, so frequently and successfully as at the first blush, in 1889, but he records here and there, in a dreary waste of experiments, that extract of the thyroid gland injected into somebody with myxœdema, has metamorphosed the patient. Constantin Paul and Professor Babes are transfusing extract of the gray matter for neurasthenia. Injections of the extract of pancreas are being tried for diabetes. In diseases of the heart, injections have been made with the extract of cardiac muscle. Dieulafoy has tried injections of extract of kidney on a man affected with uræmia. Dr. Paul Gibier kindly announces through a contributor in his own journal that he has tried extract of cat muscle in cases of progressive muscular atrophy, after failure with other methods, and gracefully adds that, "he will probably report later on this subject."

Dr. William H. Hammond, with fine insistence, appropriates all, except the hint from Brown-Séquard, of this fantastic pharmacology. He has made alkaloids of the different organs and portions of the ox, and proposes to do away with all other drugs, and cure and renew like with like, giving an eye for an eye, and a tooth for a tooth, like the Hebrews of old, while he opens up new fields to the apothecaries beyond the dreams of avarice. The medicine will come dear, but so all things do in art, and it is the simplicity and ready applicability of the remedies that must recommend them. Dr. Hammond questions whether, among all the teeming brains that have swelled and broken on the shores of time, such a solution of the vexed question of therapeutics has ever presented itself, though dimly conscious that he may have heard of some old German who speculated on the probable results of giving a liver diet to men diseased in the liver.

What pain it is to a great inventor to find that his speculations were distilling long ago in the alembic of another's brain! And yet so active have been men's minds that there are few things said, done, or conjectured, but that the spark was struck forth in immemorial days. Eighteen very old men, said Theodore Parker, could touch hands back to the birth of Christ, and in my researches into old books I never yet found one that did not allude to some book more ancient still, and to names of scholars of dates still beyond, whose monographs and treatises have clean mouldered away in the crypts of time.

As far out of the central darkness of the Middle Ages as the seventeenth century, I find in Schroeder's "Chymical Dispensatory," 1669, that the physicians of his day, upon the same hypothesis that Hammond has proceeded, and Brown-Séquard before him, used the different animal glands and tissues, in medicine, for the cure of distempers in corresponding parts in man. The work of Culpepper, 1653, gives some recipes for preparing fox lungs into a loloch for the cure of asthmas and inflammations of the lungs, and he recommends duck livers, as being exceedingly strengthening to the liver. But Schroeder, whom Cullen respectfully criticises as an authority in his day, is more elaborate in his treatise, and quotes from Crato, Baubin, Jordan, Libavius, Crollius, and others, now no longer obtainable, as I am told by librarians whom I have consulted.

In his fifth book, Zoology, he treats of that "Part of Pharmacy that shews what Medicines are to be taken from Animals," and he gives, with anxious concern, explicit directions for the choice of animals that "have no diseased dispositions," and orders that they shall be killed by external violence, to the end that "the medicamental substances of everything fit to act, shall be without diseases, and full of wholesome tinctures."

For the relief of impotence in the man, or sterility in women, he recommends the testes of the boar, and quotes Schwenkenfield as an authority for the use of the same glands from the stag, for a similar purpose. For disease of the liver, he urges the use of the liver of the calf, the hare, the wolf, and the fox. The spleen of the calf and of the fox, he asserts, will cure diseases of the spleen, and lung diseases are benefited by medicines made from the lungs of the fox. Drachm doses of the powder of wolf's

intestines would cure colics. The dried uterus of the hare, "taken after the terms, would help conception." For weakness of the bladder, he directs a sheep's or goat's bladder to be calcined and given. And in the first and second books of his Dispensatory he gives at great length the methods to be employed in preparing these animal drugs for exhibition.

But more daring than our modern therapeutists, he deals with the body of man himself, as being so much good material for medicine that it should not be wasted on a final resurrection, but should be raised up in the living bodies of those who languish. The physicians of the day employed in their practice the following parts and excrements of the living body of man: the hair, nails, saliva, perspiration, milk, secundines, spermatic fluid, and things unmentionable. And from the dead body, the flesh, the skin, the oil, the bones, the brain, gall, and heart.

The hair was said to breed hair, and a distilled liquor was made thereof, with honey, for the purpose. The sweat, seeing that it exuded from the glands, was good against scrofula. The secundines, calci ed, and given in southernwood water, cast out moles and children dead. From the semen was made a magnetic mummy to cause love, and, as Schroeder quaintly puts it, "Paracelsus makes his little man thereof." The blood was drunk hot, as a cure for epilepsy. Applied to nose or skin it stopped hemorrhages. An oil extracted from it cured consumptions. A balsam was made of it to cure the gout. Dried gently and impregnated with spirit of lemons or vitriol, and made into troches with myrrh, it cured car. buncles.

The brain of a young man under twenty-four, who had died of violence, was taken by the chemist, with all its membranes, arteries, veins, and nerves, and beaten in a mortar; to this was added the water of tile flowers, piony, bettony, black cherries, lavender, lily-convols, until it was covered four inches. After standing awhile it was distilled, and became "a brave antileptick." Salt added to the brain, and the whole distilled in a glass retort in the sand, was used to strengthen the living brain. He tells us, "if we would have more medicines made from man, we should read the particular Tractate of Becker, in Quarto."

But Dr. Shoemaker, of Philadelphia, less aspiring, could, if he would, cure anything with kola-nut. Kola-nut, chemically considered, contains about 2.3 per cent. of an alkaloid analogous to theine or caffeine; 0.023 per cent. of theobromine; together with trifling amounts of tannic acid, sugar, albumin, cellulose, starch, fat, and fixed salts. Mild enough; but with this Shoemaker had excellent results in migraine, the acute pain soon subsiding; the vomiting was relieved, and the patient entered upon a convalescence slow as usual—but more rapid than he had expected. (Now, migraine naturally takes an increasing course until vomiting occurs, shortly after which the patient is relieved, and usually falls into a sleep from which he awakes free from the headache.) In the case of a girl, aged sixteen, whose condition was due to excessive school tasks, in a hot, ill-ventilated room, without out-door exercise, kola brought about an entire change. Under its use, and withdrawal from school, she soon regained a good appetite, her headache left, and she became able to sleep at night, and, as he delicately puts it, "she now has the courage to pass a certain portion of every day in the open air." (All of which would have occurred on the girl's withdrawal from school, if the kola-nut had been still in Africa.) But he did not pause after these triumphs; he got good results from kola-nut in melancholia, neuralgia, ulnar neuritis, spurious locomotor ataxia, gastro-intestinal irritability, irregular heart, tuberculosis, dyspepsia, gastro-enteritis, renal irritation—in fact he had a whole Philadelphia drug-store in a kola-nut! He even cured boils with it, after he had first evacuated the pus! If I have done this unconscious humorist wrong, I can but recommend kola to his attention.

A sturdier faith never prompted any man to hug the iron that wounded him than appears in Dr. J. S. Whitmore, of Metamora, Ill., who for the cure of a cerebral rheumatism took black cohosh, iron, quinine, strychnia, and iodide of potash every four hours, together with phosphate of soda and tincture of digitalis every six hours. In one month he had taken one hundred and eighty drachms of cohosh, three grains of strychnia, one hundred and eighty grains of quinine, three drachms of iron, nearly two pounds of the phosphate of soda, besides his digitalis and iodide of potash. He then went to bed and changed his drug diet to ergot, gelsemium, hyoscyamus, and citrate of potash. At the end of ten days, having got no relief, he was put on extract of manaca, citrate of potash, strychnia, quinine, iron, and cactus. Being no better at the end of fifteen days, ergot was added, and citrate of lithium. In two weeks more he was convalescent, and at last accounts he was tapering off on iron, strychnia, quinine, and hydrodic acid. Here, evidently, was a man who had nursed himself on poisons from his infancy, and in his cheerful old age he could have lain down among vipers and have defied the Borgias.

I might quote largely from minor sources—of the New York young man who gives continued doses of citrate of potash, sweet spirits of nitre, acetate of ammonia, and infusion of digitalis to a man who has not urinated for ten days. At length, under the advice of a consultant, he introduces a catheter for the first time, and discovers that there is no secretion. Of the Chicago practitioner who gives a lady, for follicular tonsillitis, within one hour, ten drops of tincture of belladonna, three drops of tincture of aconite, and two five-grain doses of antipyrin, and when the patient, in alarm, tells him that she is morbidly susceptible to the influence of quinine, and begs that that shall not be given too, "he sweetly and without passion," as Ambrose Paré would say, orders a dose of it for the morning. Hastily summoned at 8 A.M., he as hastily concludes that the belladonna rash has been caused by his one grain of quinine. For no apparent reason, except that he must dose her with something, he now gives her ten drops of tincture of nux vomica, and goes home to exploit his feat in a medical journal. But I shall refrain from further illustration, only observing that this sort of dosing is going on on all sides of us.

For from times immemorial men have believed in some preternatural power in drugs; even the occult sciences have been invoked to assist in clouding any process of reasoning on their qualities. Every this or that was under the dominion of some planet, which infused into it the virtues or vices of the heathen god under which it flourished. But whatever the drug might be, it had its inevitable rise and decline. As thus, from Culpepper, 1653, of the Amara Dulcis. "It is under the planet Mercury, and a notable herb of his also, if it be rightly gathered under his influence. It is excellently good to remove witchcraft both in men and beasts, as also all sudden diseases whatsoever. Being tied round about the neck, it is one of the most admirable remedies for vertigo or dizziness in the head; and that is the reason (as Tragus saith), the people of Germany commonly hang it about their cattle's necks, when they fear any such evil hath betided them. Take notice, it is a mercurial herb, and therefore of very subtile parts, as indeed all mercurial herbs are." As far on as 1815, I find records of the esteem in which therapeutists held the amara dulcis. It would "remove felons, open obstructions of the liver and spleen, help difficult breathing, bruises and falls, and remove congealed blood in any part of the body, besides being useful in yellow jaundice, black jaundice, and dropsy."

At the close of the nineteenth century we are too ennuied to smile at the myths of ancient theology, and the god Mercury has lost his grip on the dulcamara, but it is still recorded in our therapeutics as a remedy "for cutaneous eruptions, for chronic muscular rheumatism, chronic bronchitis, whooping-cough, and other chronic

pulmonary affections; but," it is added, "it must be long continued to produce curative effects." Many patient drug-swallowers must have believed themselves in process of time to have been cured by this drug of their chronic invalidism, to the sedate gratification of the long-winded physicians who prescribed it. But note you, in the seventeenth and eighteenth centuries it cured sudden diseases, while for seventy-five years back it has only been good for chronic diseases, and now it is rarely given, so low has its popularity waned. And in recent years, Dr. John Harley laboriously experimented upon man with its expressed juice and tinctures, in small doses and in large, without any appreciable physiological effect whatever.

Would that as much could be said of many another drug that is wont to be used in season and out of season, for some of them in unguarded hands exert as desperate effects as the diseases they are reported to cure. The largely increased use and long continuance of ergot in uterine disorders, must bring about its physiological effect in time. A lady who came under my care had taken the fluid extract in drachm doses on certain days in each month, for two or three years, under the advice of a physician in a neighboring city, until she at length had feeble digestion, impaired vision, menorrhagia, increasing languor, slow pulse and respiration, and an abnormally low temperature. When the drug was prohibited she gradually recovered, during as many years, from its deplorable effects.

How many physicians know anything of the natural course of most diseases, except by hearsay? How many have had the courage to observe for themselves, while sternly combating the seductive opportunity of prescribing a variety of unnecessary medicines? Most diseases, as they are met in practice, are so overlaid, disguised, and their symptoms colored and mingled with the effects of drugs that have been administered, that only a mongrel type is known to the profession. The skilled and philosophical consultant views the case askant until he inquires what drugs have been prescribed.

Quinine, though fallen from its high estate and passing into the hands of the laity as an universal panacea, is still given frequently by the profession for a variety of disorders. It is given promptly, largely, and even hysterically, in congestive intermittents, but its physiological effect is to cause the face to become suffused, the pupils dilated, the pulse accelerated, with coma and stertorous breathing. How shall we divine between the lethal effects of disease and drug? Few recover from the congestive intermittent, and few recover from poisonous doses of quinine.

How often is gelsemium prescribed in neuralgias, congestions of the brain, and in sthenic febrile diseases, and yet even minute doses of this drug have caused alarming symptoms: the face becomes congested, the pupils dilated, the respiration slow, the brain dizzy, and death not seldom follows.

Copaiba is a favorite remedy with most physicians in vesical catarrh, but the continued use of copaiba renders the urine darker, and turbid, and irritates the bladder, causing micturition and sometimes hæmaturia.

Typhoid fever persists, ferocious, undeviating, in spite of the fifty odd drugs prescribed by the variety of physicians in attendance on a given number of cases. Some of the patients lie muttering under the spell of alcohol, some in extreme hebetude of mind lie dazed under the swooning influence of enormous doses of quinine, some lie weltering in the perspiration induced by antipyrin, but all who do not die before times continue to be prey of the riotous fiend just the same as if no powerful drug had been administered. And yet who dare aver that active medication does not imperil the sick man's chances?

Think of the saturnalia of drugs that has been administered for the relief and cure of hysteria! Ether, amber, amyl, assafœtida, camphor, castor, dracontium, galega, musk, narcissus, succini, parthenium, lead, bromides, primula, ruta, houseleek, mustard, rosemary, sumbul, tansy, linden, and thirty more. In the main, all useless, for where isolation, psychic treatment, hydrotherapy, mechanotherapy, and perhaps electrotherapy fail, outside of the valerianates and three or four other drugs, the whole host beside but aggravate the paroxysms.

The better the diagnostician, the simpler the prescription. The physician confused by the disease defends himself with a confusion of drugs. The less confidence he has in himself, the larger the army does the general gather about him, desiring to crush by numbers where his skill cannot avail.

There is a disease that ravages the earth, and many a plumed knight has gone forth to conquer it and has been himself conquered in turn. It selects its victims in hovels and in palaces, and gloats equally upon the beggar, the prince, the dullard, the artist, and the poet, the lady with the camellias and the sewing-girl in her garret. Its stealthy tread is not only in country byways, but it walks unseen in the populous mart. It destroys more lives than any other disease, not excluding the pestilence of cholera. Like the dread Angel of the Judgment, it enters all families, chooses, and is gone. So softly has it stolen that not even the parent is aware, and the lover sees only a more ethereal beauty in the face that is soon to become but a memory in his soul. Her face is flushed with kindlings of eternity, and her eyes grow large and lustrous, and fixed in their pathos as though she held reveries with unseen bands. So rapt is she that she feels not the cruel fangs upon her vitals, and were it not for the low cough that betrays the demon at his sacrificial feast, we too should be deluded into thinking the tuberculosis had abandoned his victim.

We try a hundred schemes to balk him, and to rout him from the field. Iodoform, aniline, thymol, ozone, corrosive sublimate, hydrofluoric acid, inhalations of carbolic acid, creosote, iodine, eucalyptol, turpentine, sulphurous acid, chlorine, sulphuretted hydrogen; intrapulmonary injections of iodol, camphor-carbolate, napthol, guaiacol. The introduction of the bacterium termo to war upon its natural foe, the bacillus tuberculosis: Liebrich's injections of cantharidinate of potash; subcutaneous injections of goat's blood, dog's serum, Koch's tuberculin, and Brown Séquard's fluid (Shrady). But the end is the same, and unless we resort to the ameliorating influences of climate we have tortured in vain.

I am aware that there are members of the profession who frequently give medicine, not so much from a belief that the patient's disease demands it, as from an astute sense of the fine moral effect it has, for their own benefit, on the man's friends. There are people who would be clamorously dissatisfied if a relative with an incurable disease should not be well dosed on his descent; very much after the fashion of staid old sectarians in out-of-the-way neighborhoods, who would be scandalized if one should go to heaven without benefit of clergy. And then, too, it is a convenient mask to a perplexed spirit to be industriously giving something when the case is not understood. The doctor's dignity of knowledge is not questioned—he is hard at work dosing the obstinate sick man, all must be right! "When I have a case I do not understand," confessed an old New York professor, "I give iodide of potash."

If the souls of the civilized on their last journey were suddenly rehabilitated in flesh and marched before skilful judges, it could be told in large measure to what doctors these one-time patients had belonged. One drove would be found branded with tincture of iodine wherever there had been a swelling or a pain. Some would have been snipped in their noses by the perfunctory laryngologist. Here would come a platoon wearing plasters; another, sopped with poultices; a third would have been blistered most cruelly by the inexorable quidnuncs that attended them. Drunkards with skins stabbed thick with Keeley's motors would go reeling by. Women without ovaries. Troops of sad wretches slain by fever, their stomachs

corroded by a diversity of drugs. Hospital patients yet swathed in bandages from experimental operations on hopeless diseases. Epileptics hideous from bromism. Paralytics yet quivering and gyrating, scarce escaped from the electrician. The wan victims of phthisis eloping in a mist of sprays by day, and pursued by hypodermic spearmen at night.

For after all these interminable centuries of dosing, and the ultimate skill arrived at in the profession in the selection and application of the drugs, there is no difference in the mortality-rate of most diseases from what it formerly was. The death-rate for New York City in 1892 was 24, and during the week ending April 1st, of the current year, it was 33.2. And for the year ending June 30, 1892, it was, in cities of over 5,000 population in New Jersey, 24.81 per thousand. In an estimated city population of 870,985, there died, below twenty years of age, 11,217 individuals, or one-seventieth of the entire population. Surely here was the strongest incentive of our art to rescue the bud and promise of the race, and I doubt not the zealous activity of the apothecaries, at the instigation of the profession, while the cold, pathetic Azriel lingered; but drugs could not stay this crusade to the tomb.

Upon an individual analysis of the fatal diseases in the State, for the year ending June 30th, as aforesaid, I find that 1,008 died of scarlet fever, 1,776 of diphtheria and croup, 3,575 of consumption, 5,187 of acute lung diseases, 2,242 of brain and nervous diseases of children, 2,457 of adult brain and spinal diseases, and 1,625 of digestive and intestinal diseases. And the number of deaths from the chief preventable diseases was 11,720. Altogether there died 32,685, out of a population of 1,511,653, or in other words, about one forty-sixth of the entire population died last year. If it were not for the foreign influx, where would New Jersey be in less than a generation, for the deaths exceeded the births by 2,058, in spite of the pharmacopœia.

But if this prodding stirs some saturnine brother to resentment, and he cries out testily: "What, then, have drugs done no good? Are they all equally fallacious and dangerous? How are we going to practise medicine without them?" I must return, that you have a very inferior idea of the profession, indeed, if doctors are only to be pill-venders. That drugs have done good when wisely applied goes without question. We know that opium assuages pain, the salicylates conquer rheumatism, phenacetin eases headache, pepsine assists digestion, and that men in all diseases have been comforted by the apothecary's art. But the mortuary lists of the Board of Health can furnish no monument to the living. It was Dr. Billings' conclusion in his lecture on "Vital and Medical Statistics," in 1889, that, "although the expectation of life is greater, yet this is only true of the earlier ages. After a man reaches twenty his expectation of life is less than it was fifty years ago, for the reason that more persons of feeble constitution are now nursed to manhood. The decrease in the general mortality is due to better care of infants, and the prevention of contagious diseases. So far as statistics show, there does not appear that there is any difference in the mortality-rate of most infectious diseases from what it used to be. Or if there is any difference, it is one which may be attributed to the special character of the epidemic, or the age and constitution of the people."

This being true, what are we going to do about it? The lives of the world are submitted into our hands. We have drugged the populace well, and they have not profited by it. Like great magicians, we have juggled with drugs, and have professed to cast out disease with pellets and fumigation, but we have not assumed the sublimer attitude of striking at causes. Are we to be like a swarm of lawyers and churchmen, forever following precedent—invited forward by great enterprises, but plucked backward by ghostly hands? Here and there a lonely reformer appears, but there is no unanimity of the profession. The people are apathetic because they have not been instructed. Governments are deaf because we ourselves have never been impressive.

In those ideal commonwealths, Plato's Republic, Sir Thomas More's Utopia, Bacon's New Atlantis, Campenella's City of the Sun, the art of medicine was given an inferior place, while the law-maker was exalted to the chief station. What a botch the law-maker has made in real life may be read in the uneasiness of all lands. But there is a growing anticipation as to the exalted mission of our profession, which is not confined to race or creed.

Whether the rise and fall of great civilizations is like the lifting and subsiding of monster waves, where all at length becomes a dead smooth sea, and where at best only a certain exaggerated undulation under the stress of fugitive storms is possible, or whether mankind, like a race of Titans, sometimes descends into hollows and caverns, or camps on the edges of deserts for an age, while it renews its strength for fresh encounters, and climbs again a higher range and wrests the secrets of nature from the taciturn lips of rocks, and under the cold stars wrestles with the jealous angel of the Lord, like Jacob of old, and holding fast to the divinity conquers its blessing, time is yet too young to tell. But if we might indulge in lofty anticipations which the progress of this century would seem to justify, we might in our own particular art conjecture that the day will come when physicians, as a body of public men, will be the true generals of the commonwealth. To them will be consigned the preservation of the nation, the fighting and eradication of the microscopic enemies that menace more lives and destroy more victims than all the standing armies of the world. And where a few thousands are now grudgingly doled to the science that seeks to foster the lives of men, while millions are voted annually to the art that is trained to destroy, the scale will be reversed and the public purse will be opened with alacrity to the aid of the enterprises of the guardians of the race, while the army will be cut to the smallest stipend.

No one disputes now the right of the State to conserve the public health by establishing quarantines, hospitals, asylums, the regulating of travel and commerce from ports of infection, and the general jurisdiction in sanitary affairs. It is a function that will assume vast proportions, and must come under the immediate control of the physicians of the commonwealth. Under such a régime we may expect that these officers of the State will order the affairs of the citizens so that no man shall live for private greed, but, as in ancient Sparta, each man shall conclude that he was born not for himself but for his country.

And under all their labors to eradicate infectious diseases, to enlighten the people in sanitary living; their removal of the tuberculous, the asthmatic, the rheumatic to proper climates; their modelling of tenements, inspection of food, regulating of marriage, these graver minds will read those portions of our literature with amused contempt and pity, where learned societies waste their time in disclosures and debates as to the rival claims of this or that drug, or combination of drugs, in the cure or relief of yellow fever, diphtheria, scarlatina, typhoid and typhus fever, cholera, and such like diseases, instead of striking at the root of these scourges, and with an overwhelming dictum forcing the public conscience to the only sensible remedy—the banishing of them altogether from the face of the earth.

Opium Consumers in Burmah.—A new law will shortly be put in execution in Burmah, according to the provisions of which habitual consumers of opium in that province must register their names, and the Treasury officers can issue the drug only to the people registered.

Boils.—The external use of chloral is recommended very highly in the treatment of furuncles. The boil is to be kept covered with a compress soaked in a solution containing four drachms of chloral in one ounce each of water and glycerin.

CHOLERA: SOME SUGGESTIONS FOR LOCAL AND PERSONAL PROPHYLAXIS.[1]

By JAMES LAW, F.R.C.V.S.,

ITHACA, N. Y.

The germ of Asiatic cholera is the spirillum choleræ asiaticæ, as demonstrated by Koch in the Egyptian and Indian epidemics of 1884. Among other bacteria which have been advanced as the cause of the scourge it is only necessary to mention two or three. The spirillum metschnikovi, while it resembles the true cholora germ in its morphology, biology, pathogenic qualities, and even in the color reaction of its products with sulphuric acid, yet differs strikingly in that it has never been shown to produce cholera in the human being. It is exceedingly fatal in Asia to chickens, pigeons, and guinea-pigs, producing most diastrous epizootics among the birds, but no outbreak of cholera in man habitually coincides with such bird-pest, and conversely, no such plague among the birds appears simultaneously with the frequent extensions of cholera in the human being. Klem has claimed that the bacillus of Finkler and Prior, B. prodigiosus, B. coli commune, typhoid B., and proteus vulgaris, each produces the same poison as does the spirillum of cholera, and that they render the system immune from Asiatic cholera. The fact that these bacteria are constantly with us, and that by themselves in non-cholera years they do not produce this affection, sufficiently disposes of any claim that they can generate true Asiatic cholera. Blohstein, of St. Petersburg, in his investigations in the epidemic in Baku and Astrachan, found and described two new bacteria which he considers essential factors, along with the cholera spirillum, in the causation of Asiatic cholera. He found that the cholera dejections, when inoculated hypodermically on animals produced all the symptoms of Asiatic cholera, while pure cultures of the spirillum choleræ asiaticæ did not. The first objection which presents itself is, that neither in man nor in animals have other observers found cholera propagated by endermic nor by hypodermic inoculation of the dejections; that the germ does not propagate in the blood, nor, apart from the intestinal mucosa, in the tissues. Man may handle the dejections without fear, even though he may have skin abrasions, so long as he takes due precautions against the introduction of the germ into his mouth. So in all the experiments of Koch and others in transmitting cholera to guinea-pigs, no effect whatever is produced by hypodermic or intestinal inoculation, and success only follows the introduction of the virulent germ into the alkaline intestine. It would, however, be premature to condemn Dr. Blohstein's conclusions without further experimental inquiry. The toxines of two otherwise harmless bacteria may become deadly when combined, and conversely, the most poisonous toxines may act as antidotes to each other, so that both are thereby rendered harmless. As an example of the first is the bacillus of malignant œdema, or that of Rauschbrand, which is harmless to an immune animal, but becomes deadly to the same animal when associated with the bacillus prodigiosus (Roger). As an instance of the second may be named the bacillus anthracis, which though deadly to a susceptible animal may be rendered non-fatal by inoculating at the same time with the germs or the chemical products of the pneumococcus of Friedländer, the staphyloccus pyogenus aureus, the streptococcus erysipelatos, the bacillus prodigiosus, or the bacillus pyocyaneus (Emmerich, Pawlowsky, Bouchard, Freudenreich). As a still simpler example of the effect of chemical compounds we have the fact that an animal immune from either anthrax or Rauschbrand is rendered dangerously susceptible by the addition of lactic acid. Such facts, which might be largely multiplied, should warn us against too hurried or absolute conclusions as to the influence of additional organisms and their products upon the pathogenic properties of the cholera spirillum or other disease germ. It is not improbable, therefore, that other germs may contribute to the pathogenic rôle of the cholera spirillum, rendering it specially deadly in given epidemics, or according as they may be present or absent from the alimentary canal, determining the susceptibility or unsusceptibility of the subject. Further experiment is necessary before we can confidently accept or reject Blohstein's results.

Coming back to the spirillum choleræ asiaticæ, which we must accept as the essential factor of the disease, we can now intelligently deduce from many known facts of its life-history how its pathogenic results may be warded off.

Morphology.—The cholera spirillum is a bent, twisted, mobile rod 0.8 to 2.0 micromillimetres in length and furnished with one terminal flagellum. If growth is retarded by cultivation in an unfavorable medium the different elements fail to separate from each other and become prolonged in the form of a spiral. In old cultures the individual elements are liable to show involution forms, becoming swollen and distorted at points (the arthrosporses of Huppe). The germ has, however, never been seen to produce true spores, and therefore it is much more destructible and more easily controlled than are the spore-producing bacteria. The spirillum stains best in an aqueous solution of fuchsine, and is decolorized by iodine (Grave's solution).

Biology.—The cholera spirillum is aërobic and grows well in almost any neutral or alkaline nutritive medium. Hence it is to a great extent a filth disease, clinging to soils saturated with decomposing organic matter, and maintained in an alkaline condition by the constantly evolving ammoniacal gases. This holds true alike of the filth-laden street or hamlet, or the soil charged with the decomposing vegetation of the tropics, and, above all, of the river deltas (Ganges, Nile), which receive the accumulated organic débris of a large tropical area, and expose it to the rays of an equatorial sun. This germ is, however, a facultative anaërobic organism, and can secure what oxygen it requires from the white of egg, the contents of the bowel, or, in some animals, from the blood.

It is extremely sensitive to temperature. In culture media its growth ceases below 14° C. and above 42° C. Its vitality is not destroyed, however, and on being restored to an intervening heat growth commences anew. It is killed in ten minutes by exposure to 52° C. (Sternberg), so that it is always easily and safely destroyed by boiling or an equivalent dry heat. There can be no more effectual mode of sterilizing soiled clothing, vomit, or dejections, than by exposing them to a boiling temperature. On the other hand, Babes has successfully cultivated the spirillum which had been exposed in the open air in a Berlin winter, so that the habitual disappearance of the disease in northern latitudes during cold weather must be explained otherwise than by the exposure to frost. Its extinction under such circumstances is to be attributed rather to its unsuccessful struggle for life with other bacteria at a temperature unfavorable to its vitality and growth. In ice collected from infected ponds and rivers this antagonism is not met with, and the use of such ice is therefore a means of infection.

Dried up in a thin film the spirillum dies in a few hours. There is, therefore, almost no danger from street dust, contrary to what is the case with the comparatively indestructible germ of tubercle. These two germs indeed are respectively favored by antipodal conditions. The bacillus of tubercle reaches the air-passages of man and beast through the whirling clouds of street dust, while the spirillum of cholera is preserved only in the close, narrow, sunless, damp street, where the filth is protected against dessication. Dampness thus becomes a potent factor in the maintenance of cholera in the squalid and impoverished areas of our cities, as dryness contributes to its disappearance from districts where the streets are broad, roomy, sunny, and dry.

The influence of weather is to be largely explained on the same ground. A damp, foggy, or rainy period preserves the germ against dessication and destruction, while a dry, dusty time is often the signal for an abatement of its ravages. It has been noticed that during

[1] Read before the Tompkins County Medical Society, May, 1893.

some cholera epidemics a "blue fog" hung over the surface of the ground, and that the disease abated when the fog cleared away and dry weather set in. In other terms, so long as objects on the surface of the ground were kept in a moist condition the cholera germ was preserved, whereas as soon as these were dried up it perished.

In the same way may be explained the Pettenkoffer theory of the influence of a rise of the ground-water level. When the ground-water is low the surface is dried and the surface bacteria destroyed; when, on the contrary, the ground-water rises to the surface the germs surviving in the water are brought up with it and gain an entrance into wells and other sources of infection.

As drinking-water is now recognized to be the most frequent channel of infection, it is well to note that the rapidity of multiplication of the cholera germ is to a large extent in ratio with the dilution of the medium in which it grows. Thus it is propagated much more slowly in bouillon of the density commonly employed for the culture of other microbes than it is-when the mixture has been diluted with eight or ten times its bulk of water. Extreme dilution is rather favorable to it, and it retains its vitality for several months when added to well or river water which has been previously sterilized (Wolffhügel and Riedel). In still water at 17° C. to 24° C. it multiplies in fifteen to sixteen hours. Growth is more active in pure well or sterilized water than in stagnant water charged with organic matter and bacterial ferments. This antagonism of dense nutritive solutions and of other saprophytic bacteria is strongly suggestive in several directions. The apparent purity of any well or river water which may by any chance have become contaminated is no guarantee of wholesomeness, but rather the opposite. In the impure, stagnant, and septic water the cholera spirillum is doomed to a somewhat early destruction, whereas in pure water, and, above all, in that which has been sterilized, its life may be greatly prolonged. In cultures made along with other saprophytes, and especially with B. prodigiosus, the growth of the spirillum was greatly retarded, but it was not killed (Babes). In the rice-water dejections growth is most active when first passed, but the propagation of the germ is speedily checked as the liquids evaporate and the material becomes denser and more acid. The antagonism of other saprophytes is greatly lessened if the liquids are largely diluted, and under such conditions the spirillum may take precedence of all other bacteria and form its characteristic wrinkled film on the surface (Gruber and Schottelius).

The principal sources of water contamination are the bowel dejections, vomited matters, foul clothing, house slops, especially that produced by the washing of infected houses and infected bodies. The importance of the stools and vomit lies in the fact that in man the germ is only propagated in the intestine. It fails to live in the blood or tissues, and it is only what escapes from the bowel that is to be feared. But in severe cases the discharges are so profuse as to endanger everything in the room, and therefore nothing can be considered as beyond suspicion, and nothing should be allowed to leave the room without thorough disinfection, unless it be clothing tied in a close bag to be subjected to dry heat or boiling without being opened. The house slops, if they cannot be boiled, should be made strongly acid, and left so for several hours before they are thrown out. Corpses should be burned, or wrapped in cloths wet with a mercuric-chloride solution, and buried at a safe distance from any well or water-course. No prophylactic measure can be more important than the protection of water supplies. Artesian and deep-flowing wells are safe, but rivers, ponds, shallow wells, and such as are not safely cemented against all surface leakage, are ever to be suspected during a cholera epidemic.[1] The rational plan is to boil all other water which is to be used for drinking, washing the mouth or teeth, the hands or the face, and for all household purposes.

The predilection of the spirillum for water and dilute watery solutions has a very direct bearing on the mode of development of the disease, and on its prevention and early treatment. As if to secure a proper culture-medium the germ determines a profuse secretion from the intestinal mucosa, and it may fairly be inferred that, in the absence of this, the case is destined to prove a benignant one and the patient to recover. If, therefore, the profuse secretion can be anticipated and prevented, the spirillum is likely to be repressed by the density of the bowel contents and the antagonism of the saprophytes, and the ptomaïnes and toxines are never absorbed in dangerous amount. Here is a ground for the long established opium treatment, which does appear, in certain cases, to abort the malady when employed in the very earliest stages. Here, too, is a rational explanation of the apparent benefit of the early use of aromatic oils, and of Cantani's exhibition of tannic acid by enteroclysis and by the mouth. Here, too, may be found a partial explanation of the beneficial operation of acids, aside altogether from their destructive action on the spirillum. But while opium has undoubtedly proved useful in the incipiency of the disease, its use is attended by a great danger, for if it is used after the secretion of the rice-water fluid has occurred, or if it fails to prevent such secretion, it checks the peristaltic movement of the bowels, locks up the infected culture fluid by checking peristalsis, and seals the doom of the patient. The action of opium in such a case is precisely that which Koch has availed himself of in securing the infection of the guinea-pig.

Milk, like water, forms an excellent culture-medium, and watered milk is trebly dangerous, because the water may have been contaminated, and the diluted fluid is more favorable to the growth of the germ. The milk is liable to contamination from the hands of the milker, the skin of the udder, or from dishes that have been rinsed out with cold, contaminated water, or wiped with towels that have been rinsed in such water. Where cholera exists the only safe course is to raise the milk for ten minutes to 130° F., or upward. Milk that has stood till sour is not thereby rendered safe, as the spirillum lives for two days even in milk that has soured. Another point is worthy of note. Milk which has been sterilized forms a better culture-medium than fresh milk, as it contains no antagonistic microbes, and it is prevented from turning acid, so that two influences inimical to the spirillum are eliminated. After sterilization, therefore, milk should be kept in a scalded vessel, well covered from any possible source of contamination. On milk or bouillon the cholera spirillum forms a characteristic, grayish, wrinkled, surface film, but the absence of such a film must not be taken as a guarantee of purity.

As bearing on the influence of moisture in preserving the spirillum the following data are interesting: It lives one day on rye-bread drying in the open air, three days on bread wrapped in paper, and seven days on bread covered with a bell-jar. It lived four to six days on feebly acid butter, seven days on roast meat under a bell-jar, four days on smoked fish under a bell-jar, twenty to thirty hours on dried fruit, four days on fruit under a bell-jar, one to three days on fresh cauliflower, and seventeen hours on the dried leaves of a book (Uffelmann). On apparently dry cloth it lived four to six days, while on moist cloth it lived twelve days and multiplied. It can thus find a temporary home and culture-medium on cloth as well as on the common food products, and thus the prompt sterilization of every article of soiled clothing becomes a prophylactic measure as vital as the maintenance of the purity of the food.

The growth of the cholera spirillum is always retarded by the presence of acids, and its death follows if these are in excess. Boër found that it was killed by a two hours' exposure to hydrochloric-acid solution, 1 to 1,350, or to sulphuric-acid solution, 1 to 1,300. Acetic and citric acids, and consequently lemons, lemon-juice, and

[1] In the city of Pondicherry, Hindostan, which derives its water from artesian wells and a carefully enclosed and protected reservoir, epidemics of cholera are unknown, though the surrounding country, from Madras southward, is being swept over by the plague.

acid oranges, are to be accounted prophylactic. Lactic acid in excess will destroy the germ, yet, as we have seen, it will live for two days in souring milk. The organic acids are less reliable than the mineral acids, and if these are mild or dilute their presence may fail to check the growth. Thus the spirillum can accommodate itself to the acid developed on the cut surface of a raw potato.

The free acid of the gastric juice (2 to 1,000) stands as nature's guardian for the protection of the bowel, and, during active, healthy digestion the person is safe. During abstinence, however, the stomach may be entirely empty, even of gastric juice, and the little mucus and saliva present are rather favorable than inimical to the germ. With this alkaline saliva, and, above all, with a draught of water or watery fluid, the germ may be washed on into the alkaline duodenum direct. Iced water, by actively stimulating the peristaltic movements of the stomach, is especially calculated to hasten this passage. Prolonged abstinence should therefore be avoided, and unboiled water, which may possibly have been contaminated, should be especially refused between meals. Tea or coffee made with boiling water, acid lemonade, or other acid drinks are to be preferred.

Whatever tends to derange digestion is to be avoided. The escape of the bowel—the one organ in which the spirillum can dangerously propagate itself—is contingent on the due acidity of the stomach, which must be sufficient to destroy every cholera germ that enters it. If, therefore, the gastric secretion is impaired or arrested, or if from any cause the gastric contents are hurried through the pylorus without thorough permeation by the acid liquids, the infection of a susceptible subject is rendered possible. This accessory cause is subsidiary, it is true, to the primary and essential factor of the disease—the presence of the spirillum in the food, drink, or saliva swallowed—yet in its place it is so essential to pathogenesis that it must be accorded a place in the front rank of all considerations looking toward prevention. It will not be superfluous, therefore, to identify some of the more common causes of the passage of undigested albuminoids through the stomach, and especially such as come under the direct control of the individual himself.

Drinking of water or otherwise harmless liquids to excess at meals acts injuriously in two ways: It favors the preservation and propagation of the spirillum by providing it with its favorite dilute solution, and it hastens the passage of food into the duodenum before it has been sufficiently acted on by the peptic acid.

Excess of iced water is still worse, as this stimulates the muscular coat to violent vermicular contraction, thereby adding to the force which impels undigested matters through the pylorus.

Hot coffee, tea, chocolate, or lemonade in moderate amount, are safe substitutes.

Aqueous vegetable food introduces the same element of danger. In turnips, carrots, cabbage, fresh fruits, etc., we have in round numbers ninety per cent. of water, so that they dilute and weaken the gastric acids, furnish a favorable watery medium for the growth of the spirillum, and foster other fermentations, with evolution of gas, and hurry the undigested mass through the pylorus. Once present in the duodenum these join the spirillum in stimulating a free alkaline watery secretion, and thus producing a fruitful field for the culture of the germ. As a rule, lemons and other acid fruits are protective, but we must not forget the well-known action of green apples and other unripe fruits in producing acute indigestions, which must be a prolific cause of the evasion by the germ of the gastric sentinel.

Spoiled and stale fruits and vegetables add to the above dangers that of the injurious action of the ferments already in active process of reproduction, together with their more or less poisonous ptomaïnes and toxines. These are so notoriously injurious in cholera seasons that no effort should be spared to exclude from the market whatever has started on the road to decay.

In this connection the proverbial indigestibility of certain salads deserves mention, and the injunction to confine the diet to cooked dishes is in order. The usual washing of vegetables is a possible source of infection which should always be counteracted by the sterilizing action of heat.

Unwholesome food of all kinds is dangerous as causing the derangement of the gastric secretions and motions, and the passage of undigested masses through the pylorus contributes to favor the escape of the germ. The poisonous action of many of the ferments and their chemical products demands that whenever food has started to decay it should be rigidly withheld. This applies to farinas, eggs, meats, and, above all fish, in which decay is so rapid and the products often highly injurious. Tough, fibrous, or otherwise indigestible meats are especially dangerous for invalid stomachs, as the more resistant pieces tend to pass on unchanged and carrying the still viable germs in their interior. Hurried eating and bolting the food unchewed and unsalivated introduces the same danger, which is greatly enhanced in the case of vegetable food, consisting mainly of starch, which must pass through the stomach unchanged in the absence of saliva. Eating to excess so that the stomach cannot readily digest its load, tends similarly to the passage of undigested particles and of the spirillum if present. The general resort should be to eat moderately, at regular intervals, of your customary food, taking care that it is fresh, easily digestible, well cooked, and thoroughly masticated and insalivated. If it is unavoidably tough and indigestible, cook until disintegrated and tender.

Avoid excessive exertion just after a meal. It arrests digestion, favors fermentation, and paves the way for the passage of the spirillum.

Excessive fatigue lowers the tone of the whole system, and, above all, of the stomach, thus favoring the escape of the germ and preparing the system to succumb to its poisonous products. Idleness is not to be commended; maintain the tone by regular moderate exercise, but don't exhaust the system by working to excess.

Loss of sleep and of needed rest impairs all vital functions, but none more than the digestive. This comes under the general heading of fatigue, but as it is so often incurred in the pursuit of pleasure it deserves a special note of warning against late hours and night amusements generally.

Exposure to cold and wet not only favors indigestion, but also tends to a febrile reaction and a general lowering of the vitality and resisting power of the tissues and of their protoplasmic nuclei. Many attacks of cholera have been directly traced to the predisposing cause of sleeping on the cold damp ground, and many more to the chills consequent on exposure to the night dews in clothes that were comfortable under the noonday sun. The value of a woollen abdominal bandage, and of extra clothing at night or during a cold period, must not be forgotten. For those with a weak circulation, cold feet should be carefully guarded against

Fear and all depressing passions lower the tone of the nervous system and protoplasm, and are particularly liable to impair digestion. The common advice, therefore, to dismiss fear, is no unimportant one, and to-day this can be enjoined with the confidence that there is really nothing to fear provided the requisite precautions are taken. Cholera is not any longer the "pestilence that stalketh in darkness;" it is but the fruition of a seed that cannot successfully assail man unless it reaches his duodenum, which cannot reach this viscus except through the stomach, which cannot escape destruction in the acidity of a healthy gastric digestion, which cannot survive in the absence of moisture nor in the presence of mineral acids or other disinfectants, which is easily destroyed by heat, even that which is far below the boiling temperature. A few simple precautions directed against the swallowing of contaminated articles will place a man in a position in which he need have no apprehension of an attack of cholera, even though he reside in a cholera district.

Bodily cleanliness must not be omitted. The accumu-

lation of cutaneous secretions, dust, and bacteria on the skin clothes the person in an envelope in which ptomaïnes and toxines hold a prominent place. By the absorption of these the whole system may be debilitated, and an impairment of digestion is too often an important feature of the lowering of tone. A daily soapy wash is desirable, and, if the weather should be cold, a chill should be carefully guarded against.

The habitual use of alcohol or opium is to be strongly deprecated. This may be safely based for alcohol on the notorious fatality of cholera among heavy drinkers, who always furnish a far greater relative number of victims than do other classes. The government sanitary authorities in Hindostan, who have had a greater and longer experience of cholera than anyone else, emphasize this in the following words: "The practice of drinking spirits is believed to be a certain promoter of the disease, and they should not be taken on any account" (Report on Cholera in Europe and India, Shakespeare, p. 857).

Now alcohol of ten per cent. and upward retards the growth of the cholera spirillum in artificial cultures: if therefore there were no drawback it ought to be preventive or even curative. But, as statistics show, the disadvantages far more than counterbalance the advantages. In the first place, the weaker drinks contain too little alcohol to inhibit the growth of the germ, and the stronger liquors cannot be safely taken in quantities large enough to maintain such concentration of the gastro-intestinal contents as would secure the requisite inhibition. Beer contains but from two to five per cent. alcohol, ale but eight per cent., claret ten to twelve per cent., port and sherry eighteen to twenty-two per cent., brandy and whiskey, fifty to fifty-five per cent. It requires the higher strengths to kill the germ, and no one could bring his whole intestinal contents up to fifteen or twenty per cent. and maintain it there with impunity. The rapid absorption of the volatile alcohol would speedily diminish the state of concentration, and at the same time determine a profound and dangerous narcosis. Then such large doses greatly retard the oxygenation of the blood, as shown in the experiments of Prout, Vierordt, and Smith, and as seen in the dark, bloated face of the deeply intoxicated. In this connection we must bear in mind that the arrest of hæmatosis is one of the most marked and dangerous phenomena resulting from the cholera poison, so that alcohol is increasing the peril.

Another consideration is that the habitual free use of alcohol lowers the vitality and resisting power of the leucocytes and tissue-cells, and leads them to succumb more readily to the cholera poison. It has long been recognized that alcohol lessened the antagonism to the streptococcus of erysipelas, and a serious surgical injury to a brewer's man was received almost as a death-warrant. Equally in the case of cholera the prospects of the heavy drinker are at the lowest ebb.

Again, alcohol, like opium, tends to lock up the poison within the bowel and afford it the best opportunity for a deadly proliferation. In his attempts to convey cholera to guinea-pigs all Koch's efforts failed until he injected tincture of opium into the peritoneum and thereby checked the peristaltic movements. Doyen found that the injection of alcohol had precisely the same effect, and the guinea-pig, having taken the cholera germ in a soda solution to neutralize the gastric acidity, usually fell a victim to cholera. Strong alcoholic liquors, like opium, undoubtedly tend to check peristalsis and intestinal secretion, and may thus, in certain incipient cases, moderate an attack by preventing the free serous effusion; but if this fails of accomplishment they both alike introduce the fatal condition of a more prolific intestinal culture and a more abundant production of the toxic elements.

But perhaps the gravest objection to the free popular use of spirits as a supposed preventive and cure lies in their tendency to disorder the gastric digestion, the integrity of which we have seen to be such an important factor in prophylaxis. The nausea, vomiting, and impaired digestion which result from excess, whether intermittent or habitual, opens up the best possible chance for the advance of the germ, if that has gained an entrance to the stomach. Dr. Fergus, of Glasgow, whose experience in a community who are large consumers of ardent spirits entitles him to speak with authority, says, in his instructions for the prevention of cholera: "Do not take brandy; it is not a preventive, and it does harm by disordering the action of the stomach and bowels."

For the man who habitually drinks wine in moderation with his meals it may be unwise to suddenly stop the accustomed stimulant, as the system would temporarily suffer; but if he will take the light acid wines in place of the stronger beverages, he will at once avoid this danger, and will at the same time secure a safe and valuable protection in the acid taken. Cider which has soured may be used as a substitute. For the non-habitué entire abstinence from alcohol and the maintenance of a vigorous, healthy digestion is the course to pursue.

As a refreshing drink for hot weather during a cholera epidemic, acid beverages are to be strongly recommended. Their value was strikingly illustrated by the experience of Dr. Curtin, in a Pennsylvania Insane Asylum. Two or three cases were occurring daily, but these ceased abruptly when a drink made with sulphuric acid, lemon, and sugar was supplied to the inmates. This beverage having been suspended for several days, two more cases occurred. It was again furnished, and no further cases appeared. Forty drops dilute sulphuric acid in a pint and a half of boiled, sweetened water, flavored with lemon, makes a pleasant and refreshing beverage.

Sawtschenko, in showing the existence of cholera spirillum in the intestinal canal and excrements of flies fed on cultures of this germ,[1] has made a timely contribution to the prophylaxis of the disease. It cannot be doubted that flies carry the germ on their feet as well as in their ingesta, and passing from the dejections to human food and water supplies, are chargeable with unexplained disseminations of the virus. It becomes important, therefore, to exclude flies from the sick chamber by the use of mosquito-netting or wire-screens, and to destroy any flies that may gain access by pyrethrum or other insect-poison. The prompt and thorough disinfection of all dejections, vomit, soiled clothing, and left food or water, and of all articles that have been used in the room is no less urgent. For the same reason, in cholera localities, all food should be kept under cover or screen, in such a way as that no fly nor other insect can gain access to it. Propagation through the intervention of flies is probably a main reason why cholera is so largely a hot-weather disease, and tends to die out in winter in northern latitudes. We have analogous examples of propagation through insects in the case of chicken cholera, which is easily circumscribed by a fence in winter when no flies exist, but which defies any such barrier in summer, in the fly season; also in the case of the Southern cattle fever, which prevails in the hot season, when inoculated by the wood-tick, but subsides in winter when the ticks are dormant. It has been noticed that flies disappeared during certain cholera epidemics, and it may now be questioned whether they themselves suffered from the poison, and how far their disappearance contributed to the subsidence of the epidemic.

Slight or "walking" cases present a serious danger, as no disinfectant is employed on their dejections, which may thus become the means of unexplained outbreaks. The public should be warned of the extreme danger of neglecting such cases, and it would be an excellent measure to have all cases of diarrhœa which occur during a cholera epidemic secluded in their rooms as suspected persons, and subjected to all the disinfectant precautions which are enjoined for a fully developed case. There would be considerable unnecessary seclusion, but there would be a far more perfect guarantee of the public health.

It should be understood that in all such cases, the

[1] Centralblatt f. Bakteriologie u. Parisitenk., xii., 893.

same as in those which are pronounced and unequivocal, none but the necessary attendants should be admitted to the sick chamber; the latter should neither eat nor drink there, and before doing so elsewhere should always wash and disinfect hands and mouth. So, too, with the dishes, forks, knives, and spoons used by the patient or introduced in any way into the room. These should be disinfected before removal. No food should be allowed to leave the room, and all broken victuals should be instantly burned or boiled.

A STUDY OF THE FACTORS CONCERNED IN THE RECONVERSION OF PEPTONE INTO ALBUMIN.[1]

By JAMES KENNEDY, M.D., PH.G.

MR. PRESIDENT AND GENTLEMEN: The manner of the reconversion of peptone into albumin, and the factors concerned therein, is a subject involving the process and products of digestion, and it is with the means by which this process is carried on, and the products resulting therefrom, that our paper has to deal. With reference to the process of digestion, a very brief outline will suffice for the purposes of this paper.

The elements of nutrition with which the digestive functions have to deal are divided into two classes, viz., organic and inorganic. The changes effected by the digestive functions in the inorganic or mineral compounds are relatively simple in character, and are, generally speaking, confined to the conversion of the substance into a soluble form so as to allow of its ready diffusion. The organic compounds are very much more complex in composition than the inorganic compounds, and in addition undergo changes of a much more complex character.

The organic elements of food are divided into nitrogenous and non-nitrogenous: the nitrogenous class being represented by the albuminoids or proteids; the non-nitrogenous bodies being represented by the sugars and starches. These substances (the starches and sugars) are acted upon by the digestive ferments and made to appropriate a molecule of water, and are converted into glucose according to the following reaction:

$$\underset{\text{starch}}{C_{12}H_{20}O_{10}} + \underset{\text{water}}{H_2O} = \underset{\text{glucose}}{C_6H_{12}O_6} + \underset{\text{dextrose}}{2C_6H_{10}O_5} \quad \text{and}$$

$$\underset{\text{cane sugar}}{C_{12}H_{22}O_{11}} + \underset{\text{water}}{H_2O} = \underset{\text{glucose}}{2C_6H_{12}O_6}$$

With reference to the proteids or albuminoids, the change seems to be almost identical—that is, so far as the appropriation of a molecule of water is concerned.

It now becomes necessary to consider the constitution of these substances. The constitution of a proteid or albuminoid substance is represented by the formula CHNOS. Many varieties are included under this general formula. Most of these compounds are amides, which are acids in which amidogen, NH, has been substituted for OH, hydroxyl. The proteids are divided into seven principal classes, namely: 1, Native albumins; 2, derived albumins; 3, globulin; 4, fibrin; 5, peptones; 6, coagulated proteids; 7, lardacein.

There are certain characteristics which serve in a general way to differentiate these several classes, and there are certain reactions, more or less distinctive, by which the members of each group may be identified. It may be well to state, at this point in our paper, that while this is true in a certain sense, it is also true that, owing to the fact of the uncertain composition of these bodies, we know of no means by which any one of these bodies may be identified with that degree of certainty which characterizes the analysis of other bodies of more definite composition, such as the inorganic compounds.

The digestive ferments which are the active and essential factors in the process of digestion are nitrogenous bodies, and are of an exceedingly complex character, and, so far as my knowledge extends, have never been separated in an absolutely pure state, nor has their exact composition ever been accurately determined. This much, however, we have learned and can prove, that they are capable, under proper conditions, of causing a pronounced change in both the physical and chemical properties of all of the organic elements of nutrition.

The gastric juice, with its hydrochloric acid and its pepsin, acts upon the albuminoids in such a way as to convert them into peptone, a substance capable of diffusing through an animal membrane; while the pancreatic juice, with its trio of ferments, is capable of effecting the same change in an alkaline medium through the agency of the ferment trypsin which it contains, and is also capable of converting starch and cane sugar into glucose and of emulsifying fats by the aid of the ferments amylopsin and steapsin, which are also elements of this secretion.

Now, the sum total of the products of digestion is represented by the blood, which contains serum albumin and certain reconstructive elements which have been elaborated by organs possessing this function. Chief among the constituents of the blood is albumin, which seems to constitute the *pabulum vita essentialis* of the body, and is derived from the proteid elements of food furnished to the digestive system.

If we follow up the changes through which an albuminoid body goes before it becomes serum albumin, we find that the first transformation to which it must submit in the presence of a digestive ferment is the conversion into either acid or alkali albumin, according to the portion of the alimentary tract where it is found.

The second change it undergoes is into peptone or "diffusible albumin," and after absorption it again becomes albumin.

Now, if ordinary egg albumin, coagulated, be boiled with either acid or alkali, it may be rendered soluble, but it cannot be made to pass through an animal membrane by any means that we know of, save by being subjected to the action of one or the other of those complex bodies known as pepsin and pancreatine.

The generally accepted view regarding the composition of peptone is that it is a highly hydrated form of albumin; and inasmuch as an acid media is required for the action of the first-mentioned ferment, and an alkali media for the second, it would seem that the primary step in the conversion of albumin into peptone is effected by one or the other of these agents. It is quite probable that, in either case, the albumin combines chemically with the substance, whether acid or alkali, and an extra molecule or more of water is necessary to the stability of the compound; and this new compound (soluble albumin), being presented to a hydrolytic ferment, is induced to undergo a molecular transposition, which results in the breaking up of the compound, causing a further appropriation of the elements of water and a setting free of the acid or alkali element.

This theory seems to be borne out by the fact that a definite amount of the ferment pepsin—say one grain—is capable of digesting an unlimited amount of albumin, if the digested material be removed and the temperature, degree of acidity, and proper dilution be maintained, and also by the fact that neither acid nor alkali is necessary to the existence of peptone after it is formed, and also by the further fact that a solution of acid albumin will be precipitated by the addition of an alkali or an alkali albumin by an acid.

Among the substances capable of being thus formed into peptone are: albumins (native and derived), the globulins, fibrin and lardacein, and the peptone resulting from the digestion of these different substances always possesses the same properties.

When proteid substances are presented to the digestive secretions they are at once transformed into peptone. The peptone is absorbed, and is immediately changed into albumin.

The question arises, by virtue of what factors or agency is this transformation effected? Can it be due to the influence of the absorbents themselves? It does not seem

[1] Read before the Texas State Medical Association, at Galveston, Tex., May, 1893.

probable, inasmuch as a solution of peptone may be made to pass through an animal membrane without any change whatever in its composition. After having diffused into the vessels it comes immediately into contact with the blood, and naturally we should look for some element of that vital fluid to be the cause of this change. The blood is composed of a liquid and a solid portion. The liquid portion is an albuminous fluid, the serum, while the solid part consists of red and white corpuscles. The fibrin factors are also contained in the blood. It being a well-known fact that the red corpuscles do, by virtue of their containing hæmoglobin, carry oxygen to the tissues of the body, it would not be unreasonable to suppose that they exerted an influence in the production of the phenomenon of transforming peptone into albumin. On account of the fact that the hæmo globin enters into a loose chemical combination with the oxygen, I thought it possible that the transformation might possibly be due to a process of oxidation, and that the oxygen being in such a loose state of combination and yielded up with such facility that it might possibly be appropriated by the peptone. Experiments which I have made, however, lead me to believe that they play no essential part in the change.

In order to demonstrate the possibility of nascent oxygen transforming peptone into albumin, I added a solution of peroxide of hydrogen to a solution of peptone, and boiled the mixture; but no evidence of the presence of albumin could be found in the mixture. I next placed a dializer containing a solution of peptone into a vessel containing a solution of peroxide of hydrogen, and afterward tested for the presence of albumin; but not a trace could be found. Experiments with deoxidizing agents were performed with solutions of peptone; but in no instance could a trace of albumin be obtained.

The only other elements in the blood that might be capable of exercising any influence in the conversion of peptone into albumin are the white corpuscles and the fibrin factors (*i.e.*, fibrinogen, fibrio-plastin, and the fibrin ferments). Since an intimate relation between the white corpuscles and fibrin factors seems to have been proven, it did not seem worth while attempting to consider their possible influence in this direction separately. I proceeded, therefore, to obtain some fresh blood and a fresh solution of peptone. I obtained a solution of peptone by digesting the coagulated albumin of a hard-boiled egg, by means of pepsin and hydrochloric acid, and separated the peptone from any acid albumin that might have been present by means of dialysis. I obtained plasmine from the blood by means of the saturation method with magnesium sulphate. I prepared a solution of plasmine with distilled water, and added a measured volume of this solution to a measured volume of peptone solution. In another tube I placed a volume of distilled water equal to the volume of the peptone solution, and added a volume of the plasmine solution equal to the amount added to the peptone solution, and then placed both tubes in the flame of an alcohol lamp and heated to boiling. A precipitate of albumin occurred in both tubes; but the amount of precipitate was larger in the tube containing the peptone solution than in the tube containing the distilled water and the plasmine. The experiment was repeated many times, frequently with both beef and dog's blood, but in every instance the same result occurred.

Plasmine, as is well known, is a compound substance, being made up of fibrinogen, fibrino-plastin, and fibrin ferment; hence by our experiment, although it seems to prove that plasmine is capable of reconverting peptone into albumin, we do not know whether it be due to one or the other of these agents, or to all three combined.

I will state that I have not been able to precipitate para-globulin from blood serum by the carbonic-acid method, although I have tried several times to do so. I did, however, obtain by the saturation method a substance which reacted with peptone just as plasmine did.

I have obtained from blood serum, by means of the saturation method with magnesium sulphate, a substance possessing a light brown color which was soluble in water and coagulable by heat. A solution of this substance gave the same reactions with a solution of peptone that were obtained with a solution of plasmine, viz., converted it into albumin.

Owing to the impracticability of separating the fibrin factors in the pure state, it is impossible to state which one of them is responsible for the change. There are very many difficulties attending the separation of these elements from the blood: for instance, the difficulty of keeping the blood liquid for a sufficient length of time, and the almost impossibility of washing the precipitate thoroughly on account of its great solubility in water; and last, but not least, the fact of the absence of any means within the range of our knowledge by which we can determine the purity of either one and its freedom from contamination by the others.

While I am strongly of the opinion that some one of what we call the fibrin factors is responsible for or plays a very important part in the conversion of peptone into albumin, I am conscious of the fact that my experiments were exposed to many sources of error. To prove this fact positively it would be necessary to make a quantitative estimation of the peptone and also of the coagulable constituents of the plasmine solution, and at the end of the reaction a quantitative determination of the coagulated albumin would then be necessary for an absolute verification of this theory. These determinations I have not been able to make, owing to the uncertain composition of these bodies and the present state of our knowledge.

Clinical Department.

A CASE OF HOMICIDAL MANIA.

By ERNEST HELM, M.D.,

BELOIT, WIS.

PHYSICIANS are often called upon to listen to strange, humorous, pathetic, or horrible stories; but seldom has it been my lot to hear a more frightful one than a patient related to me last night.

He told it so simply and graphically that I can do no better than give it in his own words.

He is a carpenter, of powerful physique, while his wife is a delicate, slender woman. The events occurred about three years ago and are strictly true, and illustrate to a remarkable degree the wonderful cunning of some insane patients. He said:

"My wife had often acted strange before, but had never attempted violence, so I was totally unprepared for what happened. We had retired as usual, when between 11 and 12 P.M. I was suddenly aroused from sound slumber by violent and repeated blows on the head.

"Frightened, confused, bleeding, I sprang from my bed, and in that hideous darkness I grappled with my unknown assailant. We had a fearful struggle for the mastery, when at last I wrenched a stout club from my opponent's hands and was about to use it with all my force, when my wife laughed and said in her usual tone of voice, 'Ben, I had to do it.'

"Until she spoke I had no doubt but that I was assailed by a burglar or a midnight assassin. On lighting the lamp I found the club was a heavy hickory mallet-handle.

"A physician was called who treated my wounds, though I will bear long scars to my grave.

"Nothing new happened during the rest of the night, and the next night she went to bed as usual, while I kept watch. My head pained so that I could not sleep, and anyway I dared not sleep.

"Early the next night she said, 'I want a drink,' and when I volunteered to get it for her, she savagely told me 'to mind my own business, she would get it herself.' I said, 'All right, suit yourself,' for I made it a point never to cross her, except when absolutely necessary, and then to be firm and unyielding.

"She arose, went to the water-pail in the next room, in plain sight of me, stood there rigidly for a brief time, and then suddenly went out of sight into the pantry. I at once arose to follow, when she laughed and returned to bed. Wondering what her object could be in going to the pantry I determined to investigate when she went to sleep. Soon she became quiet, her breathing deep, and regular, so I feigned sleep by nodding in my chair, closing my eyes, and allowing my paper to fall to the floor. Through my half-closed eyes I watched her: she soon half arose, her eyes gleaming like a snake's, and eyed me intently. When I aroused she dropped back in bed in her former position so quietly and suddenly that I doubted my senses as to whether she had ever stirred. After a while, feeling sure she was asleep, I went out through the kitchen into the pantry, and my blood ran cold when I found two large butcher knives laid out for me. Returning to see if she still slept, I found her apparently as I left her, so I went again to the pantry and took the knives out of doors and threw them away in the grass.

"All this time I heard no sound, and it was impossible for her to see me from the bed or the room where she was.

"Her brother soon came, and as she still slept and I was very tired and in great pain, I arranged for him to watch her, cautioning him not to close his eyes for one instant. I then went upstairs, but the floor had settled so I could not quite shut the door. I dared not go to sleep with an unlocked door, so I took a large stove zinc and noiselessly placed it against the door in such a position that the door could not be opened without knocking the zinc over and thus arousing me. I slept little, but toward morning I fell into a light sleep, but soon awoke, feeling that someone was climbing the stairs. I listened intently and soon knew she was coming. She approached the door, and though it was opened only two inches (and from the inside, so a person on the outside could not see the zinc at all) her slender hand and arm crowded in, grasped the zinc, and noiselessly removed it. I then said, 'What do you want?' She laughed and said she wanted me 'to get up for breakfast.' She then descended the stairs, and forgot to take the large carving-knife she had carried up to use on me. She had laid it down when opening the door. I found her brother had gone to bed and was sound asleep.

"It was now 4 A.M. and quite light. She had had him build the fire and go to bed, while she busied herself getting breakfast. I then went out to secure the knives in the grass. She came to the door, so I pretended to be out to view the beauties of the early morning sky; but she said: 'Oh I brought those knives in an hour ago.' This startled me greatly! How did she know those knives were there? The grass was too long to find them by accident. She could not have seen me from her room or bed when I threw them out, and I am sure she remained in bed.

"Then how did she know the zinc was against my bedroom door? I placed it there noiselessly, and it could not be seen from the outside. She was soon adjudged insane and sent to the hospital for the insane.

"I see her often now, and while sane on many points, and often asking me to take her home, she will never promise not to assault me.

"She only says that she 'cannot bear to have me buried alive, and if she does not kill me I will surely be buried alive.'

"Oh! it was a terrible experience, and her first midnight assault was so deadly and hideous that I shudder whenever I think of it."

This experience is worse than many of the terrible things in fiction, but I can personally vouch for every word of it.

Gastric Ulcer.—Give neither food nor medicine by the mouth, but rely upon rectal alimentation.—DONKIN.

Progress of Medical Science.

The Treatment of Gangrenous Intestine.—In a certain proportion of cases of strangulated hernia the bowel is found in a gangrenous condition, and the treatment of such cases in the past has practically been limited to relieving the constriction and to the creation of an artificial anus. The mortality under these circumstances is very considerable, in fact, the discovery of gangrenous intestine has hitherto been looked upon as an indication of the hopeless nature of the case. Judging from a paper read by Dr. Kendal Franks before the Medical and Chirurgical Society, these cases are not as hopeless as statistics would lead one to infer (*Medical Press*). He urges with some show of reason, basing his conclusion on a tolerably extensive array of statistics, that resection of the gangrenous gut with immediate suture affords the patient a much better chance of recovery. Nor was this conclusion seriously questioned by the experienced surgeons who had assembled to hear what the author had to say on behalf of a procedure that certainly strikes one as severe, considering the usually very depressed condition of such patients. The discussion turned mainly on the question as to whether the operation should be completed on the site of the original wound made for the relief of the femoral or inguinal hernia, or whether, after the preliminary palliative measure, it should be performed through a median abdominal incision made for the express purpose. Opinion on the whole was in favor of the resort to abdominal incision, and this is probably the view that will commend itself to most unprejudiced surgeons. It is evident that the thoroughness of the examination of the gut and the freedom of manipulation could never be the same through such a small aperture as that afforded by the inguinal or the crural canal—apertures, moreover, which cannot be safely enlarged. By this procedure the mortality has been reduced from something like ninety-five to about fifty-six per cent., a brilliant enough achievement considering the very unfavorable circumstances under which it is necessarily undertaken. One point that came out very clearly in the discussion was the impunity with which relatively considerable lengths of gut can be removed. One case was mentioned in which over a yard had been removed, and this without interfering with the recovery of the patient. It is indeed all-important to remove every inch of damaged tissue, otherwise no suture, however perfect, can be relied upon to hold. A very large proportion of the failures after enterectomy are attributable to non-compliance with this salutary rule, and it cannot be too strongly impressed on surgeons that the kind of suture is of far less importance than the fact of its being applied to healthy tissue. There must, of course, always be cases which come under treatment at such a late period that nothing can be done. These "too late" cases are the operator's horror, for they weigh down the statistics with an unduly large proportion of fatalities, although death has really nothing to do with the operation *per se*. Dr. Franks has called attention to a means of rescuing a certain proportion of patients otherwise condemned to inevitable death, and he has succeeded in divesting gangrenous intestine of half its terror.

Catarrhal Fever in Children.—According to Laine (*Medical News*) the diagnosis from the symptomatic fevers is made: 1. From the simple continued fever, or febricula, by the higher range of temperature, its epidemic character, and longer duration. 2. From thermic fever, by the presence of laryngeal cough, and the fact that it occurred both in epidemic form and at all seasons of the year, irrespective of temperature or weather. 3. From typhus or typhoid fever it might be frequently impossible to differentiate, especially during the presence of these diseases in epidemic form. In the typhoid fever of children both diarrhœa and spots are often wanting. The abdominal symptoms are slight, the fever likely to assume

a distinctly remittent type, and on the whole, running a shorter course than in adults. The spleen is, however, always enlarged; the nervous symptoms are prominent; bronchitis is usually present; epistaxis rarely occurs; and the mortality is low. According to Dr. George B. Wood there is an extraordinary susceptibility to the action of cathartics in the disease under consideration. The presence of herpetic eruptions on the lips and face is also said to exclude its existence in children. 4. Relapsing fever, by the absence of enlarged spleen or liver, of jaundice and articular pains. 5. From tuberculous meningitis it might be quite a difficult matter, since cases are mentioned in which, notwithstanding the presence of extensive cerebral disorganization, there were no convulsions or evidences of paralysis. On the other hand, its abrupt commencement, and the absence of strabismus, irregularly in the pupils, arhythmical pulse and respiration, constant and peculiar vomiting, and violent screams, should exclude the existence of meningitis. Only in its more rapid onset and higher range of temperature do the symptoms of acute meningitis differ from those of tuberculous inflammation of the membranes of the brain. 6. From acute general miliary tuberculosis I doubt whether it could be distinguished, except by the usual fatal termination of the latter. 7. From malarial remittent fever, by the absence of chills and sweats, but above all by the careful examination of the blood with a view of determining the presence or absence of Laveran's plasmodium. 8. From yellow fever it would be a difficult matter, especially in countries in which this disease is prevalent all the year round. In fact, Guiteras is authority for the statement that yellow fever in the tropics can only be diagnosticated from the simple continued fevers of children by the fact of the increased mortality from meningitis, dentition, malarial remittent fever, etc., occurring during certain seasons of the year. 9. From central or abortive pneumonias, there should be no doubt in the diagnosis after the first few hours. 10. From catarrhal pneumonia, or broncho-pneumonia, by the change in both the character and frequency of respiration, the absence of all abnormal physical signs in the chest denoting catarrhal fever, and a dry cough out of all proportion to the local symptoms. The advent of catarrhal pneumonia is slow and insidious in children, but we should always be able, no matter at what stage of a prolonged fever, to detect its presence by the physical signs, the increased temperature, or its greater remissions during the day and changes in the character of the cough, which would become looser and more frequent.

Of the treatment of catarrhal continued fever there is little to be said. Antipyretics had little or no effect on the course of the fever, and although quinine was given in large doses, both by the mouth and in suppositories, its effects were, on the whole, disappointing. In fact, more reliance was placed on treating hyperpyrexia in these little patients by tepid baths than on the use of internal antipyretics. The baths not only reduced the temperature, but to a certain extent also relieved the great irritability from which the patients all seemed to suffer.

Retrograde Changes in Trichinæ and their Capsules.—Dr. Langerhans, of Berlin, reports a case of trichinosis in the person of a woman who died in the wards of the Charité Hospital, aged fifty-one years. The parasites were found in enormous numbers, particularly in the diaphragm, in the intercostal muscles, in the muscles of the neck, of the eyes, the tongue, and in both pectoralis major and deltoid muscles. As nearly as could be ascertained, the only time in the life of the patient when the invasion of these parasites could have taken place was in her twentieth year, during the manifestations of a supposed articular rheumatism; from which it may be assumed that they had been present in her person for thirty-one years. A small proportion of the organisms were yet living, the duration of their supposed parasitic existence being the longest on record; but by far the greater number were dead and more or less altered. Inasmuch as the changes of these parasites after their death have received little attention, and references to such changes are infrequent and indefinite, the author has classified the various conditions in which he found these parasitic bodies in this case with such an apparently prolonged duration. In many the capsules were unchanged, the trichinæ dead and calcified, some with their forms preserved, others broken into larger or smaller fragments; about many of the capsules was a variable amount of fat-tissue, especially about the poles, and in some instances there was to be seen, in addition, a round cell deposit, either about the poles or all around the periphery of the capsules. In some cases the unchanged capsules presented an absolutely empty interior, while others, unchanged in size and appearance, were filled with connective tissue, here and there being changed into adipose tissue. There were to be seen, too, degenerated capsules containing fragments of calcified trichinæ, or entirely empty, or filled with fibrous adipose tissue. Some of the appearances were to be regarded simply as atrophied, shrunken, empty, or sclerosed capsules; and here and there there were spots in the tissue which seemed to be the former position of parasites and their capsules, but which no longer showed anything save small patches of connective tissue. From these descriptions it is to be supposed that these parasites, together with their envelopes, are subject to degenerative conditions, and that they eventually and naturally reach a stage of elimination from the body of their host. It is probable that this process of removal is accomplished sometimes, in part, at least, through the agency of a connective-tissue formation; but it is likely that it may also take place without it. The author states that he cannot confirm Müller's belief that the removal of the parasites occurs by a fatty degeneration, or Leukart's, that they are resorbed without having first been calcified. It is probably correct that the parasites undergo this calcification before the capsules do, the latter undergoing this change soon after the death of the parasite, sometimes before the resorption of the trichina is complete, sometimes after its complete removal. The recovery from the invasion of the parasites is not, therefore, complete with the calcification of the trichinæ, but with the total elimination of both the animals and their envelopes.—*International Medical Magazine.*

The Functions of the Gastric Mucous Membrane.—At the Twelfth German Congress of Internal Medicine, Wiesbaden, Von Mering detailed some interesting experiments made to elucidate the absorbent power of the gastric mucosa, the results of which investigations were as follows (*The Boston Medical and Surgical Journal*): The evacuation of the contents of the stomach takes place at intervals by means of the rhythmical opening of the pylorus. A liquid aliment escapes more quickly from the stomach than a compact aliment such as meat or bread, even when strongly impregnated with water. The stomach is an organ of excretion much more than an organ of absorption. It does not absorb water. When water charged with carbonic acid is ingested, the stomach does not absorb the water, but it absorbs largely the CO_2. Alcohol is absorbed in large proportion by the stomach. Sugar, of whatever kind, is absorbed in moderate quantity when in solution in water, and in greater quantity when in alcoholic solution. Dextrine and peptone are absorbed by the stomach, but in less proportion than sugar. The quantity of substances absorbed augments with the degree of concentration of the solution. Chloride of sodium, iodide, and bromide of potassium are absorbed in notable proportion. Conjointly with the absorption of the aforenamed substances, there is produced in the stomach an aqueous secretion, more or less active, whose importance is generally in direct relation with the quantity of substances absorbed. There is an abundant secretion of water in the stomach, even when there is no free HCl secreted. Gastric absorption resembles in many respects the physical process of diffusion (endosmosis and exosmosis). Gastric dil-

atation, in cases of pyloric stenosis, is due not only to the pressure and bulk of the aliments introduced and stagnating in the stomach, but also to the augmentation of volume of the contents of the stomach by reason of the quantity of water furnished to the stomach by the organism (endosmosis) in ratio of the proportions of nutritive substances which penetrate the blood from the gastric cavity (exosmosis). From a therapeutic point of view it is well, then, in cases of gastrectasis to exclude alcoholic beverages, and to advise the ingestion of nutritive substances in a state of concentration, as well as consecutive lavages of the stomach. To combat the thirst, it is better to give lavements of plain water, or salt and water, than to allow the patient to drink water, as the indication is to limit as far as possible the excretion of water by the stomach. Dr. Unverrecht, of Magdeburg, in commenting on the paper of Von Mering, said that he had himself observed that in cases of dilatation of the stomach, water is badly absorbed and the urine scanty, and he has deduced therapeutic conclusions similar to those of Von Mering. In such cases a dry diet, lavage of the stomach, and lavements of a weak solution and common salt, prescribed methodically, not only give real relief, but cause an increase in weight; for in a case where the dilatation was due to carcinoma, he has seen the weight increase five pounds in eight days under the influence of this treatment. Ewald, who was also present, stated that the clinical observation of diseases of the stomach has enabled him to study the various forms of dilatation and their stages. In gastrectasis patients eliminate more water than they ingest, hence the name gastrosaccorrhœa applied to this condition. His experience was largely corroborative of the conclusions reached by Von Mering. The experiments of the latter were made with healthy adult dogs, in which pyloric fistulæ were established.

Aural Vertigo in Children.—Dr. Lannois maintains that aural vertigo may appear in children either as a transitory epiphenomenon or as a manifestation of an acute lesion of the auditory apparatus; recurring, however, at intervals of varying duration, in association with chronic disease of the ear; it is much more rare in children than in adults. He reports four cases. One was in a child of seven that had measles and whooping-cough at two, followed by chronic otitis media. The second case was in a child that had, for eighteen months, suffered with vertigo and vomiting, and that presented cicatricial adhesion between the tympanic membrane and the handle of the malleus. The third case was in a child of seven that had scarlatina two years previously, and thereafter the symptoms of aural vertigo. The fourth case was in a child of eight that had suffered some impairment of hearing after a fall at the age of five, and that presented symptoms of aural vertigo following an attack of influenza. Attention is called to the possibility of mistaking the attacks for those of epilepsy, but the loss of consciousness in the one condition and the occurrence of vomiting in the other should be distinctive. Of sixty deaf-mutes, but six presented vertigo and nausea. Children who still heard a little seemed more liable than those that were entirely deaf.—*Medical News.*

Surgical Intervention in Tumors of the Dura Mater.—Dr. Delagénière has described a case of sarcoma of the dura mater in which, after trephining, extirpation of the tumor, with resection of the dura mater, the patient made a good recovery. He submits the following conclusions: 1. Perforating tumors of the cranium, whatever their nature, have a special form of development. 2. In the majority of cases they originate upon the external surface of the dura, dissect it from the bone, perforate the bone, raise the integument, and finish by perforating it. 3. Anatomically they may be considered as pedunculated, having a base internal, a neck corresponding to the opening in the skull, and a subtegumentary intra-cranial portion. 4. Surgically they are pediculated tumors originating from the dura, and the removal of that portion of dura and the tumor guarantees their total enucleation. 5. To remove them it is necessary to exsect the external portion and sufficient bone to uncover the base: they should then be removed by morcellement, and finally the dura resected, the entire portion upon which the tumor rested being taken away.—*Archives de Chirurgie.*

Destruction of the Pituitary Gland.—In the *Revista sperimentale di Freniatria*, vol. xviii., December 31, 1892, may be found the results of thirty experiments upon dogs and cats in reference to the effect produced by complete destruction of the pituitary body. Complete destruction of the gland proves rapidly fatal. Partial destruction is also fatal. But in this instance the process of dissolution is sufficiently slow in some cases to be carefully followed. There is a marked change in the character of the animal due to the profound prostration that is present. There is muscular weakness, together with clonico-tonic convulsions. Difficulty of breathing is noted; anorexia alternating with boulemia; polyuria, urine watery and very alkaline; polydipsia, low temperature, and emaciation out of all proportion to the anorexia. All these conditions are improved by injections of extracts of the pituitary gland. The inference is that the destruction of this gland is followed by the formation and the accumulation within the organism of some special toxic substance.

Hæmatocele Simulating Appendicitis.—At a recent meeting of the Clinical Society of London (*The Lancet*) Mr. Barker described a case of subserous uterine hæmatocele in a girl, aged eleven, simulating acute appendicitis; laparotomy was performed with success. Taking the view that the child was suffering from the latter disease in a most typical form, Mr. Barker opened the abdomen in the right linea semilunaris, over the cæcum, but found the latter and the vermiform appendix perfectly normal. Some turbid, brownish serum, without lymph, flowed from the direction of the pelvis, and feeling in this direction the right Fallopian tube and ovary were found to be swollen and twisted, and when brought into view were seen to be quite black from blood effused under their serous coats. Tracing this effusion inward, it was found to expand into a large subserous hæmatocele behind the uterus. This tumor nearly filled the pelvis and corresponded with the swelling felt per rectum before the operation. This brownish serum in the pelvis had probably transuded from it: it was quite smooth on the surface and was inflamed. The condition was now recognized, and it was felt that no attempt should be made to remove the blood tumor. The serum was therefore sponged out and the abdomen was closed in the usual manner. The child made an uninterrupted recovery. On leaving hospital on the thirty-first day after the commencement of the last attack, the hæmatocele, as felt from the rectum and vagina, had diminished in size. The patient was watched for a month or two subsequently, but there was no return of the symptoms suggesting any attempt at very early menstruation. The case was recorded as possessing pathological, clinical, and surgical interest, and as being probably a rarity: Mr. Barker was unable to find any account of a pelvic hæmatocele in a girl so young as the patient in question.

In discussing this case, Mr. Treves dwelt upon the difficulties referable to the anatomical site in diagnosing appendicitis, and cited two cases illustrating this. One was that of a boy who exhibited all the classical signs and symptoms of intussusception, but on opening the abdomen to relieve the obstruction, the condition was found to depend upon gangrene of the vermiform appendix. This was removed and the patient recovered completely. The other case was diagnosed, after consultation between two medical men, as enteric fever, and was sent to the Fever Hospital, being subsequently transferred from there to the London Hospital, where the abdomen was opened in due course and the appendix found glued by inflammatory adhesions to the ileum opposite a Peyer's patch, which may have accounted in part for the close simulation to typhoid fever. After removal of the appendix this case also recovered.

MEDICAL RECORD:

THE HYPODERMATIC TREATMENT OF SYPHILIS.

DR. J. WILLIAM WHITE, of Philadelphia, has girded himself to the task of settling the question of the value of the hypodermatic method in the treatment of syphilis. He has discharged his work well, and has, we should judge, established the position of this mode of practice very definitely (*University Medical Magazine*, May and June, 1893). After describing the various preparations recommended and giving the supposed indications and the alleged results, he proceeds to quote the experience of a large number of authorities upon the subject of hypodermatic injections. These authorities are almost uniformly against the practice. Some of the Germans (Kaposi, Neumann) advise them only as a last resort, and consider them below inunctions in value.

Fournier says: "My opinion is that it is not a good treatment. The injections are painful, they interfere with the patient's avocation, they necessitate frequently repeated visits. Above all, the method is not practicable. In private practice patients will not tolerate it. In hospital practice it is possible, but note the result. Patients leave the Du Midi and Lourcine, where this treatment is employed, and flock to the St. Louis, where they know they will not receive it."

In England, Hutchinson, who is *facile princeps* the leader of the British syphilographers, says: "Hypodermic injection has come but little into employment in English practice, nor does it appear to increase in favor with those continental surgeons who at one time thought highest of it."

Dr. L. B. Bangs, of this city, says: "I instituted some experiments a few years ago, in private practice and in my service at Charity Hospital, which satisfied me that the hypodermatic method of treating syphilis was so rarely useful as to be valueless. Moreover, the claim that it 'cures syphilis in a much shorter period,' etc., will not hold, for in my opinion it takes just about so long to 'cure' the disease, whatever may be the method of treatment employed. The effect of hydrargyrum upon a symptom can be obtained by the other methods with no pain and with less risk than by the hypodermatic method."

Nearly all the prominent specialists in this country concur in this opinion.

Dr. White thinks from the evidence collected that it is safe to conclude—

1. The hypodermatic treatment of syphilis has not as yet shown results which warrant its adoption as a routine method to the exclusion of, or in preference to, other methods, but, on the contrary, has some apparently insuperable disadvantages, and even dangers, which render it improbable that it ever will be so adopted.

2. The circumstances under which hypodermatic medication should be employed may be summarized as follows: *a*, Those cases in which other methods of treatment have been tried and failed; *b*, those cases in which, owing to idiosyncrasy or intercurrent disease, the skin and the digestive tract cannot be used for the introduction of mercury; *c*, those cases in which, owing to grave and advancing lesions, rapid mercurialization is absolutely necessary; *d*, those cases in which obstinate localized lesions can be most directly reached by this plan: *e*, possibly those cases referred to by Jullien, in which early differentiation between syphilis and malignant disease, or tubercular ulceration, is extremely important, should be included in this list; I certainly feel inclined to employ the method in all doubtful cases which admit of it, particularly in those conditions of the tongue which often leave the surgeon for a considerable time in doubt as to their exact nature; anything which promises to shorten this period of doubt, by rendering the therapeutic test more rapid and more certain, would be of great advantage; I should, however, in such instances, feel obliged to use potassium iodide by the mouth at the same time: *f*, a theoretical possibility of the employment of mercury hypodermatically has suggested itself to me, but I have not as yet actually employed it. It may be that its use by this method will aid in shortening the period of doubt which often intervenes between the appearance of the primary sore and the development of general adenopathy, or of the exanthemata. If in the presence of a sore of uncertain character the employment of mercury hypodermatically resulted in rapid cicatrization, no local treatment being employed other than cleanliness, it might occasionally throw light upon the case without being open to all the objections which attend the systematic and slower administration of mercury by the mouth. It is possible that the idea is worth a trial in exceptional cases, but I do not think it should be adopted as a routine practice.

3. As to the choice between the two great classes of mercurials, the soluble salts are to be preferred to the insoluble in the large majority of cases as more exact in the matter of dosage and much less dangerous and less likely to be followed by local disturbances. They are always to be used when there is need for rapid mercurialization.

The insoluble salts should probably be reserved for those cases in which frequent visits to the surgeon are impossible, and in which no contra-indications exist. In cases of defective kidneys, diabetes, profound anæmia, marked atheroma, great debility, etc., such methods are dangerous, and the case, even if urgent, will probably do better under some other form of treatment.

4. Finally, as to the special preparation to be employed: Among the soluble salts the bichloride is probably to be preferred. The results from its use are not strikingly different from those obtained from the other compounds of this class, but its stability and great solubility and its germicidal qualities seem to warrant its selection. The disadvantage is the pain which it causes, but the evidence in this direction shows that in the hands of impartial inves-

tigators not responsible for the introduction of the particular substance employed each of the salts on the list produces a considerable amount of pain and a not inconsiderable number of accidents or complications. Probably the bichloride is freer from objectionable features in respect especially to the production of suppuration than any of the salts of mercury.

Dr. White seems to have put an effectual quietus on the fad of treating syphilis by hypodermatic injections.

THE MOVEMENT OF THE MEDICAL POPULATION OF NEW YORK.

"The Medical Register" for 1893–94 contains a list of 2,550 physicians practising in this city, and 3,539 in the State, exclusive of New York and Brooklyn. The lists of previous years, respectively, are as follows for the city and State:

	City.	State.
1893–94	2,550	3,539
1892–93	2,435	3,394
1891–92	2,325	3,165
1890–91	2,265	3,161
1889–90	2,085	3,073
1885–86	1,902	2,775
1884–85	1,789	2,685

The New York City list is admittedly not complete, there being about nine hundred other physicians of various grades and kinds. The figures show an increase of physicians in this city during the past nine years of 761, and in the State, outside of New York and Brooklyn, of 854. The ratio in this city has been about one hundred more proportionately than in the rest of the State. The population in the past nine years has increased just one-half a million, *i.e.*, from 1,356,958 to 1,827,396.

To provide for this half million increase there has been an increase of 761 in the regular physicians, besides a good many others of not sufficient standing to get into the Green Book. This means one new physician for every 650 new arrivals, and as thousands of new arrivals are poor immigrants, the supply is quite sufficient.

On the whole, however, the figures quoted do not show any extraordinary increase in the supply of medical men. The enormous difficulty and labor required to secure a remunerative practice in New York are facts but too well known, and they naturally deter many from undertaking the task.

The annual loss by death from the city list is over forty; the number that move away or give up practice is not known, but in 1889 it was 70; the average annual increment over and above losses is 93; so that it may be said that between 200 and 250 new practitioners establish themselves in this town annually. We wish them all success.

THE BEST PREPARATIONS OF IRON.

There is no drug in common use whose preparations are so numerous as are those of iron. Professional reputations and the fortunes of commercial institutions are linked with one or other of these. An interesting story could be told of the "fashion in iron" or "ferric fads." The popularity of Bland's pills came in with Niemeyer's text-book, and this preparation held sway for a long time. It is still in good repute. Dialyzed iron was for several years considered a most potent and palatable promoter of corpuscular richness; the albuminates, the malates, pomates, formates, and peptonates have all been warmly recommended. The Flint tablet, the syrup, various modified tinctures and essences have been the vogue for a longer or shorter time.

If one were to apply the rule which generally holds in therapeutics, viz., that when many remedies are warmly recommended for the same malady all are equally good or bad, we should have to conclude that iron was always iron, and that the kind of preparation employed made little difference.

With the proper instruments of precision, however, we can at the present time make a surer diagnosis and watch more closely the effects of remedies. Dr. Andrew Smart, of Edinburgh, has brought such methods into use in studying the value of the different iron salts (*The Lancet*, February 25, 1893), and he has reached some conclusions which ought to possess more than ordinary value.

Dr. Smart's first conclusion is a somewhat surprising one. It is to the effect that of all the preparations of iron the sulphate is the best. This applies not only to cases of anæmia, but also to those of chlorosis. In atonic dyspepsia with deficiency of hydrochloric acid ten or fifteen drops of this acid should be given before each meal, and the iron after it. In cases with acid dyspepsia with pyrosis, on the other hand, bicarbonate of soda should be given before eating. Next to the sulphate, preparations of the carbonate of iron were most successful given in doses of twenty or thirty grains of the saccharated powder thrice daily.

Third on the list stands the syrup of the protochloride. A drachm of this preparation contains seven grains of the salt. It is not tolerated by the stomach as well as the sulphate or carbonate. The phosphate and protoxide were somewhat uncertain in their action.

Arsenic, when given alone, did not seem to have any appreciable effect on the anæmia, but combined with the sulphate of iron it increased the activity of the latter drug. In pernicious anæmia, however, this statement does not hold good, since here arsenic distinctly increases the richness of the blood in corpuscular elements.

THE REPORT ON THE REVISION OF THE CODE.

The Committee on the Code of Ethics of the American Medical Association presented a majority and minority report, on neither of which was action taken. The majority report advised leaving out from the Code that part which deals with the obligations of the public to physicians; it recommends that physicians be permitted to patent mechanical devices and to consult with all legalized practitioners. It expresses its belief in the need of a Code, and it defines very casuistically the nature of a consultation.

The minority report takes more conservative ground and recommends that the Code stand, practically, as it is.

We doubt if any good will come from continuing to discuss these questions. We prefer to teach the gospel of righteousness and let the details be determined by the individual conscience. The individual conscience, we may add, is setting strongly toward consulting with all qualified practitioners who enjoy a reputation for honesty among their fellow-men.

News of the Week.

Does the Kidney Move? — Mr. Henry Norris, in a lecture on "Some Changes in Surgical Opinion, Regarding Diseases of Urinary Organs," says:

"Floating or movable kidney is an entity about which the most divergent views have been and still are held. A few years ago it was gravely asserted by a distinguished surgeon that movable kidney was a myth; that it was a thing of no pathological significance; that the literature of the subject was based not on post-mortem experience but on clinical impressions which were fallacious; that the cases of supposed mobile kidney were in reality tumors of other organs—*e.g.*, the gall-bladder, ovarian cystomata, and diseases of the head of the pancreas; that in the few cases of mobile kidney recorded as having been observed at post-mortem examinations the condition had not been suspected during life; and that a righteous scepticism ought to be entertained as to movable kidney being the cause of real suffering. Somewhat similar doubts were suggested, if not actually expressed, at a recent meeting of the Royal Medical and Chirurgical Society, when Mr. Bruce Clarke read a paper on 'Acute Renal Dislocation.' Two of the speakers referred to the rarity of movable kidney in the post-mortem room, and one stated that though he had made four thousand post-mortem examinations he could remember but two cases of movable kidney. A third speaker, who has contributed to our knowledge of actual cases of the sort, attached but little importance to the clinical effects of movable kidney, for he said: 'Women who are the subjects of this condition suffer from a little occasional dragging pain in the side, but otherwise usually have no symptoms.' Many, too, consider that the wearing of a belt is all that is requisite to relieve what little inconvenience is caused, that nephrorrhaphy ought not to be performed, and never succeeds; and lately it has been prognosticated that in a few years we must expect to hear of renal calculi having developed upon the sutures used to transfix the kidney in this operation.

"On the other hand, the opinion is held that movable kidney is an every-day experience in practice, that a very large minority of women are thus constituted, and that it is by no means uncommon in men. I hear of patients being told on no account to submit to nephrorrhaphy—firstly, because it is very dangerous, and, secondly, because it is unnecessary for a condition with which twenty per cent. of the human race pass through life. In 1888, Dr. Lindner, a German physician, brought out a work on the 'Anatomy, Etiology, and Diagnosis of Floating Kidney in Women,' in which he boldly declares that this condition is the most frequent anomaly in the female, that one woman out of every five or six is the subject of it, and that he is prepared to face the most violent opposition in support of his assertions. Laudau, Skorezewsky, Roberts, Newman, and many others might be quoted as authorities on the question of movable kidney. Surely on a matter of fact of this kind it is time that the professional mind arrived at a definite and decisive conclusion. There is abundant evidence existing in support of it, and for the last two hundred years at least, authorities of the highest repute have recorded well-authenticated cases, while the report of the committee of the Pathological Society of London, in 1876, ought to have placed the matter beyond dispute."

Doing Away with the Communion Cup.—A Methodist church, in Ohio, has voted to substitute for the sacramental cup used at communion, a sufficient number of individual glasses.

Physicians Stand by Each Other. — Staten Island seems to be a place where brotherly love reigns. Some time ago the physicians of the Smith Infirmary at New Brighton resigned on account of the action of the trustees. Recently the trustees have offered to reinstate three out of the five visiting physicians; the offer was declined because it did not include all of their number.

Pan-American Medical Congress.—The following is the full text of the report of the Committee on Permanent Organization of the Pan-American Medical Congress to the American Medical Association, Milwaukee, Wis., June 6, 1893: "Your committee appointed at Washington to effect a permanent organization of an inter-continental American Medical Congress, begs leave to submit its final report as follows: An organization has been effected under the style and title of the Pan-American Medical Congress, to be held at the City of Washington, D. C., September 5, 6, 7, and 8, A.D. 1893, under the Presidency of Professor William Pepper, M.D., LL.D., of Philadelphia. The details of the organization are set forth in the published preliminary announcement of the Congress, copies of which are respectfully submitted herewith, in both English and Spanish, as a part of this report. Since the publication of this preliminary announcement an organization has been effected in Paraguay. Your committee is therefore pleased to state that an organization of the Pan-American Medical Congress exists in every State and Territory of the United States, and in every remaining country and colony of the Americas, including the West Indies and Hawaii. A provision has been adopted since the foregoing publication whereby every medical society—national, colonial, and local—has been made a constituent organization of the Congress. The committee begs leave to report further that the organization which has been effected as above, and which, by the authority you have conferred upon it, has been and is already very actively engaged in carrying out the practical ends of the Congress. The Senate and House of Representatives at the first session of the last Congress adopted a joint resolution, authorizing the President to extend an invitation to the Governments of the Western Hemisphere to send official delegates to the meeting, and to appoint similar delegates on behalf of our own Government. This official invitation has been issued through the Department of State, and all replies so far received have been in the nature of acceptances. The President has indicated that the Government of the United States will be represented at the Congress by six delegates. At the last meeting of the Executive Committee of the Congress a resolution was adopted directing that in view of the Columbian Exercises in progress in America this year, and in view of the relations which have become intimate between the United States and Spain, that the Government of the latter country be requested to send delegates to the Congress. It was thought that the exceptional relations of amity existing between the two countries would warrant a course

which has been avoided with regard to all other European countries, out of deference to the interests of the International Congress which is to meet in Rome. The National Congress at its last session appropriated $15,000 for the purposes of entertainment of the meeting. The President of the United States has consented to open the Congress in person, and to extend the courtesy of a reception at the White House to delegates and their families. A special feature of the Congress will be the proceedings of the sections on hygiene, climatology, and demography, and on marine and hygiene quarantine. The proceedings of these sections will be largely of the nature of a sanitary conference with particular reference to practical questions of public health and of imminent importance. With this object in view, every municipality of the three Americas, including the West Indies and Hawaii, has been invited to send an official delegate, and a very large number of acceptances have already been received. The titles of several hundred papers, accompanied in many instances with abstracts, have already been received from representative medical writers in the English, Latin, French, and Portuguese countries. This, of itself, assures the scientific success of the Congress. Invitations have been extended to representative European scientists to be the guests of the Congress, and a number of acceptances have been received. In conclusion, your committee begs leave to express its appreciation of the spontaneous response to its appeal for funds in the form of advance registration fees from the public-spirited representatives of our profession in America. Let it be remembered, no registration fees will be accepted from members of the Congress residing outside the United States. Although money has been realized from advanced registrations in amount sufficient to pay some of the preliminary expense of organization, a still larger sum is needed with which to meet accumulated obligations. It should be held in mind that the Congressional appropriation, meagre as it is, will be available only for purposes of entertainment at the time of the meeting, and that the expense involved in publication, correspondence, and clerical work is necessarily very heavy and must be met at once. The members of the profession are therefore again urgently requested to register at once by paying the fee ($10) to the treasurer, Dr. A. M. Owen, Evansville, Ind. Those who thus become members of the Congress, but who may be prevented from attending the meeting, will receive a set of the Transactions, which, of themselves, promise to be worth more than the amount of the registration fee. In submitting this, its final report, your committee begs leave to thank the Association and its executive officers for cordial support, and the medical press for its energetic and efficient aid in promoting this earnest movement for the unification of the medical profession of all the Americas. Respectfully submitted on behalf of the committee, CHARLES A. L. REED, Chairman."

Gifts to Harvard Medical School.—Dr. Henry W. Williams, for many years Professor of Ophthalmology in the Medical Department of Harvard University, has promised the medical faculty $25,000 for the endowment of a full professorship of ophthalmology. The Departments of Physiology and Pathology have received a gift of $10,000 from Miss E. Ellis.

The Medical Department of the Army.—Surgeon-General Sternberg has decided upon the establishment of a school for post-graduate instruction to the newly appointed officers of the Medical Corps of the Army. The course of instruction will be given in the Army Medical Museum in Washington, and will be of four months' duration. It will be conducted by four of the senior medical officers stationed in the capital. The general order providing for the establishmemt of the army medical school, issued by Adjutant-General Williams, is as follows: By direction of the Secretary of War, upon the recommendation of the Surgeon-General of the Army, an army medical school will be established in the city of Washington for the purpose of instructing approved candidates for admission to the Medical Corps of the Army in their duties as medical officers. The course of instruction will be for four months, and will be given annually at the Army Medical Museum in Washington City, commencing on November 1st. Four professors will be selected from among the senior medical officers of the army stationed in or near the City of Washington, and as many associate professors as may be required to give practical laboratory instruction in the methods of sanitary analyses, microscopical technique, clinical microscopy, bacteriology, urine analysis, etc. The faculty of the Army Medical School will consist of: 1. A president of the faculty, who shall be responsible for the discipline of the school, and who will deliver a course of lectures upon the duties of medical officers in war and peace (including property responsibility, examination of recruits, certificates of disability, reports, rights and privileges, customs of service, etc.). 2. A professor of military surgery (including the care and transportation of wounded). 3. A professor of military hygiene (including practical instruction in the examination of air, water, food, and clothing from a sanitary point of view). 4. A professor of clinical and sanitary microscopy (including bacteriology and urinology).

The Surgeon-General has also determined upon a change in the system of assigning medical officers for duty as attending surgeons to officers and their families in New York, Boston, Chicago, Philadelphia, Baltimore, San Francisco, and St. Louis. The custom heretofore has been to give these details of three or four years to the older medical officers of the army, but it is now intended to detail medical officers who have only recently attained the rank of captain. The tour of duty will last only one year. By this system the medical officer selected will be enabled to become familiar with the practice of the leading physicians and surgeons in this country, and to attend medical lectures and meetings of medical societies. The experience and observation will fit them the better for their second examination, which is required by law before they can be promoted to majorities.

The Summer Corps of the Board of Health began work on July 5th. The corps is composed of fifty physicians, each one having charge of a district in which he is expected to visit and inspect every tenement-house, reporting on its sanitary condition, and prescribing for the sick poor who may be unable to pay for medical attendance.

An Autograph of Hahnemann.—At a recent sale of a large collection of dramatic literature, Americana, etc., in this city, a framed autograph letter, written and signed

by Dr. Samuel Hahnemann, the founder of homœopathy, was disposed of. The letter was written at Paris, in 1841, when Hahnemann was eighty-five years old, and its subject was an inscription on a tablet which was to be placed on the house in Meissen, where he was born in 1755. It was sold for $20.

The French Association for the Advancement of Science will meet this year at Besançon, on August 3d, and will continue in session one week. The president of the Association is M. Bouchard. The work of the Association is distributed through seventeen sections.

A Hospital Ship on the Coast of Labrador.—The mission ship Albert, despatched by the London Mission to Deep Sea Fishermen, for work among the needy and sick fishermen on the coast of Labrador, has arrived at St. John's, N. F. Dr. Grenfell and two other medical men were sent in the ship, as were also two nurses. Two hospitals on the coast have been built by wealthy St. John's merchants, and one of the doctors will be in charge of each. The ship with the other doctor will cruise up and down the coast. The Albert has a steam launch, presented by two English gentlemen, which will be of great use along the coast, and her cargo of supplies, most of it contributed by wealthy English people will be distributed gratuitously among the needy fishermen. The work will close in October.

Dr. Benjamin A. Fordyce, of Union Springs, died June 3d, aged seventy years and four months. He had naturally a good constitution, and had always enjoyed excellent health, attending to the duties of his profession until attacked by his last illness, a severe form of typho-malarial fever. He commenced the practice of his profession in 1844, after attending Geneva Medical College. During the Civil War, he was for several years Assistant Surgeon in the One Hundred and Sixtieth Regiment, New York Volunteers. After the war he removed from Venice to Union Springs, where he settled permanently. He was the oldest member of the Cayuga County Medical Society, in respect to years of practice, having joined in 1844. He was at one time president of the New York State Medical Association, and was a member of the Central New York Association of the American Medical Association, and at the time of his death was president of the Cayuga County Protective Medical Association. He was a High Priest of the Masonic Chapter for several years. He enjoyed the confidence and esteem of all who knew him. He married Emeline Slocum, in 1845, His wife and three children survive him.

The American Medical Association will hold its next meeting in San Francisco in the spring of 1894.

Dr. William H. Broadbent, who attended the Duke of York, during an attack of typhoid fever some time ago, has just been created a baronet by the Queen, in honor of her grandson's wedding.

Cholera in France.—There were 704 deaths from cholera in the southern part of France, during the month of June; 138 of which were in Marseilles, 53 in Cette, and 51 in Toulon.

The American Neurological Association will hold its next annual meeting at Long Branch instead of Saratoga, as was first announced. The sessions will take place on July 25, 26, and 27, 1893. The following is the preliminary programme: "The Diagnosis of General Paresis," by Dr. L. C. Gray, of New York; "The Genesis of Hallucination, Illusion, and Delusion," by Dr. H. A. Tomlinson, of St. Peter, Minn.; "A Study of the Temperature in Twenty-five Cases of General Paralysis of the Insane," by Dr. Frederick Peterson, of New York; "Observations on a Case of Myxœdema," by Dr. William C. Krauss, of Buffalo, N. Y.; "Etiological Significance of Heterogeneous Personality," by Dr. Smith Baker, of Utica, N. Y.; "Tumor Involving the Angular Gyrus," by Dr. G. L. Walton, of Boston, Mass.; "A Case of Acromegaly, with Autopsy," by Dr. C. L. Dana, of New York; "The Anatomical Changes in the Spinal Cord in an Old Case of Infantile Paralysis—A Contribution to the Cell Grouping in the Cervical Cord," by Dr. Joseph Collins, of New York; "Some Observations on the Relation of Chorea to Rheumatism, with the Narration of a Case," by Dr. C. Eugene Riggs, of St. Paul, Minn.; "Thyroidectomy in the Treatment of Graves's Disease," by Dr. J. J. Putnam, of Boston, Mass.; "Experiences in the Use of Testiculine and Cerebrine," by Dr. J. J. Putnam, of Boston, Mass.; "Tabes and Syphilis," by Dr. B. Sachs, of New York; "The Paroccipital Fissure," by Dr. B. G. Wilder, of Ithaca, N. Y.; "Report of a Case of Infectious Endocarditis, with General Septicæmia, Complicated with Multiple Neuritis," by Dr. James H. Lloyd and Dr. David Reisman, of Philadelphia, Pa.; "Progressive Muscular Atrophy—The Pathological Report of Two Cases, with the Exhibition of Microscopical Specimens," of Dr. G. M. Hammond, of New York; "Lesion of the Thalamus and Internal Capsule in a Case of Hemianæsthesia, with Notes of Autopsy," by Dr. Charles K. Mills, of Philadelphia, Pa.; "A Report of Two Cases of Friedreich's Ataxia," by Dr. Frank R. Fry, of St. Louis, Mo.; "Exhibition of a Brain from a Case of Mixed Aphasia, with Lesion Confined to Broca's Region," by Dr. George G. Preston, of Baltimore, Md.; "Peripheral Paralysis after Surgical Operations," by Dr. V. P. Gibney, of New York; "A Case of Chorea of Sydenham, with Autopsy," by Dr. C. L. Dana, of New York; "A New Form of Pedometer," by Dr. William C. Krauss, of Buffalo, N. Y.

Scarlet Fever in London in 1892.—According to the Annual Report of the Chairman of the Metropolitan Asylums Board of London, the total number of scarlet fever patients received during the year 1892 amounted to 13,093, and exceeded by 6,556 the largest number admitted during any previous year. The greatest number of patients suffering from all classes of fever and diphtheria under treatment in the hospitals at any one time was 4,389.

Rabies in India.—In a number of cases of hydrophobia recently occurring in India, so says the *Indian Medical Record*, the period of incubation has been found to be almost invariably three months. The disease has been noted especially in Calcutta, Bombay, and Benares, and stringent police measures are being enforced for the destruction of all stray dogs.

The Ice Consumed in Paris has been found to contain a number of pathogenic microbes, among others the bacillus of typhoid fever, and the Conseil d'Hygiene has advised the enforcement of measures looking to a supply of ice from purer sources.

Society Reports.

American Medical Association.

Forty-fourth Annual Meeting, held in Milwaukee, Wis., June 6, 7, 8, and 9, 1893.

(Special Report by Telegraph to the MEDICAL RECORD.)

(Continued from p. 27.)

SECTION IN OBSTETRICS AND DISEASES OF WOMEN.

THIRD DAY, THURSDAY, JUNE 8TH.

A New Operation for Uterine Fibroids, with Report of Cases.—DR. FRANKLIN H. MARTIN made a second supplementary report on his new operation of vaginal ligation of a portion of the broad ligament of the uterus for uterine tumors. The operation consists in the ligation from the vagina of more or less of the broad ligament with its vessels and nerves, the extent of the ligation depending upon the result sought, from a simple ligation of the base of the ligament, including the uterine artery and branches of both sides, without opening the peritoneum, to a complete ligation of the ligament of one side, including both uterine and ovarian arteries, with partial ligation of the opposite ligament, without opening the peritoneal cavity, if possible, but doing so if necessary.

The doctor reported five cases. Two of these were reported in his first report of the operation. The result in the five operations were given up to date.

CASE I., in which the operation was incomplete on account of insufficient ligation of one ligament, has not resulted as favorably as one could wish. Tumor not materially affected. Hemorrhages ceased temporarily. Subsequent reports show hemorrhage increasing again. The patient thinks that the tumor has increased somewhat.

CASE II.—Patient had large tumor, eight by five inches in diameter, and suffered severe pain and constant hemorrhage for several years. In a state of complete invalidism. Patient left hospital on the eighth day. She was operated on December 3, 1892. I have seen this patient every month since the operation was performed. The hemorrhage has ceased completely. There has been very scanty flow at the menstrual period. All pain has ceased. The uterus had materially reduced in size at the end of one month. At the end of three months it was but little larger than a normal uterus. The patient's health had improved so that, from a state of almost complete invalidism she was transformed into a comparatively strong and healthy woman. The improvement was progressive from the day of the operation.

CASE III.—Married woman of about thirty, no children, with a bleeding interstitial fibroid of the uterus, enlarging that organ to diameter of four by three inches. The tumor was so comparatively small that I decided to ligate but one side. The patient was out of bed in ten days. The results have not been ideal. The flow has been decreased in quantity. One month after the operation, at the time I saw her last, there had been no appreciable change in the uterus. She writes, four months after the operation, the flow is about one-third the time of duration, and one-third the amount that it was formerly. Otherwise not improved.

CASE IV.—Mrs. S——, aged thirty-six. Menstruation has always been profuse and has been constantly increasing since the age of twenty. Last five years, till thirteen months ago, has had profuse flowing, twenty-one days in each month, while the last thirteen months it has been constant and exhaustive. Patient confined to her bed. Suffers severe pain much of the time. December 19th, in the presence of the post-graduate class, I made an exploratory for the purpose of removing a uterine tumor if possible, or of removing the appendages. I was unable to accomplish either operation on account of universal intestinal adhesions over surface of the growth. The abdomen was closed, and when the patient was sufficiently recovered to stand another operation, I performed my operation on her. This was January 5, 1893. On account of the comparatively large sized tumor, filling as it did the pelvis almost completely, and extending to the umbilicus above, the operation was a difficult one. I succeeded, however, after considerable dissecting, in including the entire base of each ligament, with its principal blood-channel and branches. The flowing ceased immediately and the patient was relieved of her drain for over two weeks. She then had a few days' flowing which resembled an ordinary menstruation. She has rapidly and steadily improved since that time. She has menstruated regularly, but scantily and without pain. She can at this time, five months after the operation, attend to her duties as a housewife, and considers herself cured. The tumor has reduced in size until it is no longer noticeable as a deformity, and so that the patient herself is no longer conscious of its presence.

CASE V.—Married: age, thirty. When referred to me by Dr. Geer, of Chicago, there had been constant hemorrhage for three months. Diagnosis, fibroid tumor about size of four months' pregnancy. Patient operated on January 8, 1893. Had a little subsequent temperature; and one month after ligature from left broad ligament came away from becoming infected from the vagina. Four months after operation the menstruation only lasted two days, very scanty, no pain. Fibroid diminished in size until uterus is about normal. Patient claims that she is cured.

Dr. Martin predicted an important future for this operation.

Prolapse of the Female Pelvic Organs.—DR. HENRY PARKER NEWMAN, of Chicago, said it was his desire in this paper to call attention briefly to prolapse of the female genital organs, with particular reference to their hernial nature, regarding them as having a similar etiology and the same pathological significance as hernia in other situations, and amenable to analogous lines of treatment.

Like cephalic, thoracic, and abdominal hernia, the etiology of pelvic hernia comprised such predisposing causes as defective development, including congenital malformations and inherited tendencies, depraved muscular tone through debilitating disease, and trauma; while the majority of these cases were generally attributed to traumatism, this might often in itself be the result of defective development, and inherited or acquired weaknesses or malformations.

Prophylaxis in the formative stage of puberty, as well as in pregnancy and labor, was of the utmost importance. Operations upon the pelvic floor or vaginal walls, while indispensable in their place, could not be relied upon alone to cure all herniæ of pelvic viscera. The ideal treatment was to be found in the combination of operations for repair and those for accessory support from above, and these might all be accomplished at the same sitting, saving the delay and annoyance of repeated operations.

Cocaine—Its Uses in Gynecology.—DR. WILLIAM H. HUMISTON, of Cleveland, O., read the paper. Having had five years' experience in the use of cocaine in gynecological operations, he felt better prepared to eulogize its merits now than he could do two years ago, when he first brought the subject before the Association in Washington. He had then stated that the only annoying symptom that frequently arose was the shortness of breath and the anxiety connected with it; this he had been able to obviate by the use of strychnia or tincture of nux vomica, one-thirtieth grain of former, or fifteen minims of the latter, administered with one-half ounce of whiskey thirty minutes before operation.

He performed the following operations with no other anæsthetic than cocaine, viz., dilating, curetting, trachelorrhaphy, anterior and posterior colporrhaphy, and perineorrhaphy, frequently making two of these operations at one sitting. The essentials of the methods were: asepsis, pure cocaine, quantity, and how used. He prepared the cocaine in two strengths, four and ten per cent., the first for hypodermic use and the latter for intra-uterine injec-

tion preceding curetting. The quantity at one sitting varied from three-quarters to two grains.

Discussion on the four preceding papers was then taken up.

Dr. Carsten thought if one was going to use strychnia he should use strychnia, not nux vomica. The latter was of varying strength.

Dr. Mitchell, of Cincinnati, had used cocaine in minor gynecological operations, but found it unsatisfactory, producing alarming symptoms.

Dr. C. P. Reed was also afraid of cocaine.

Dr. Mordier, of Kansas City, thought Dr. Martin's operation would be useful, but only in a limited class of cases. He said the circulation was only in part to blame for symptoms in fibroids, the nerves should be considered. Dr. Martin replied to this criticism that his ligature included nerves as well as arteries.

Dr. Griggs, of Buffalo, had reduced fibroids by hypodermic injection of ergot, but he would now try Martin's method.

Dr. K. W. Hoff had, in one case of uterine fibroid as large as a pitcher, injected daily two to three grains of ergotine over the region of the broad ligaments, and in seventy-five days the tumor, also a nævus of the size of the hand, had quite disappeared.

Dr. Humiston thought pelvic hernia due to subinvolution of the uterus following laceration of the cervix, the perineum being only of secondary importance in supporting the uterus.

Ectopic Pregnancy: Its Comparative Symptomatology and Treatment.—Dr. Joseph Hoffman, of Philadelphia, read on this subject. Those who had most widely argued the possibility of exact diagnosis had had the least abdominal experience. They believed that it was possible to say positively that this or that swelling was the result of an ectopic gestation, because they did not understand the various train of pathological conditions that had their manifestation in pelvic fulness, tenderness, throbbing, and the like.

In a given case we could say that here we have a disease in which the probability of the presence of an extra-fœtal pregnancy could often be safely affirmed after certain periods. First, after rupture; second, after the fœtus had become viable; third, the presence of discharging fœtal remains, either through the bladder, rectum, or umbilicus. But it was most ridiculous to consider the last condition under the head of diagnosis.

As to the diagnosis previous to rupture, it need hardly be considered, for our attention was called to the case only by the symptoms of rupture. The diagnosis must be after the conclusion that a pregnancy existed. We could then judge by the conditions whether the case was one of ectopic gestation.

Winchel's assertion that ectopic gestation was more readily diagnosticated than the normal condition, was one which was safely left with himself. It was hardly worth while to dispute it. His abdominal experience had not been sufficient to justify his sweeping statements in diagnosis. The treatment was only by cœliotomy.

Extra-uterine Pregnancy.—Dr. A. H. Cordier, of Kansas City, read only that portion of his paper relating the history of a case of extra-uterine pregnancy, the specimen being presented. A few years ago extra-uterine pregnancy was considered very rare. During his brief experience he had seen an unusual number. The past two years he had operated or assisted in sixteen cases. The duration of pregnancy had been between six weeks and two years. In all cases the pregnancy was at first tubal, and rupture must always take place into some part at some time unless there was arrest of growth.

Intra-peritoneal was to extra-peritoneal rupture in the proportion of three to one. Where rupture was intra-ligamentous the fœtus could live.

The specimen presented was from a woman, aged twenty-four, operated upon April 15, 1893. The pregnancy dated from August, 1891, symptoms of rupture in October. She had felt fœtal movements up to April, 1892, or nine months after conception. False labor pains came on. She began again to menstruate, December, 1892, and was regular until March, 1893.

The diagnosis before operation was uncertain, but ectopic gestation was the one most acceptable. When the incision was made down to the tumor, it was noticed that the knife cut down upon the growth at the lower angle of the vascular membrane; this was tied in sections. This tying and cutting process had to be tied around the middle of the tumor. On the upper and posterior aspect of the growth an intestine was found attached nine inches. This had been brought about by the mass, or it had ascended out of the pelvis, stripping the peritoneum from the posterior wall of this cavity and separating the layers of the mesentery up to the gut by the same gradual process that early in the pregnancy had pulled apart the two layers of the broad ligament. After making a complete circuit of the growth (amnion) the tumor was easily lifted from the bottom of the pelvis. This locality did not require a single ligature. At the left side of the uterus, near the tubo-uterine junction, the peritoneum was so firmly attached to the uterus that the organ was cut into and gave rise to considerable hemorrhage. This was controlled by a stitch or two, and the membrane was divided at a greater distance from the uterus. The tumor being taken out, the peritoneum was lifted up from the bottom of the pelvis on that side, hemorrhage being controlled by water. Irrigation and drainage were used.

She did well. The mass contained a full-formed eight-pound child. The sac was filled with the fœtus and placenta. The placental site was at the top of the sac. The rupture had evidently, he said, been into the broad ligament where the fœtus went on to develop.

Dr. Howard A. Kelly had had three cases of extra-uterine pregnancy which had gone to term; the child had died, and in about six months afterward he saw the woman, and operated by the only method which he thought was satisfactory—complete extirpation of the fœtus, with sac, membranes, and placenta. The vessels having shrivelled, there was less danger from hemorrhage than when the fœtus was living. Dr. Kelly formerly disbelieved in intra-ligamentous pregnancy, but had seen one undoubted case, shown to be so by the pathologist.

Dr. Boldt had seen three cases of undoubted intra-ligamentous fœtation.

Dr. Davis, of Birmingham, Ala., thought the child could not have been taken out in the sac as it was had it not been in the broad ligament, and asked Dr. Joseph Price's opinion on this subject; and Dr. Price said he did not think there was any evidence of the case being one of rupture into the broad ligament and development there. He had never seen such a case, and believed tubal pregnancy always ruptured into the peritoneal cavity, not into the broad ligament.

Accouchement Forcé in Certain Obstetrical Complications.—Dr. Lewellyn Elliot, of Washington, D. C., read this paper. He defined accouchement forcé as labor actively begun and terminated by artificial aid, either with dilators, tampons, Barnes's bags, or the fingers. He urged as his opinion the superiority of the fingers over all the mechanical devices in use, as well as the most harmless. This mode of practice was indicated in cases of uræmic convulsions, either threatening or in existence, rigid os, placenta prævia, uterine inertia, and other conditions requiring artificial aid. He deplored the fact that books and journal articles were silent upon this old method, and quoted Charpentier, Winchel, and Lusk as being opposed to it. He denied that the method would be attended by untoward effects—post-partum hemorrhage, laceration of the cervix, uterine inertia—more frequently than by other means. He recited the histories of four cases where the method had been employed by him—two of uræmic poisoning, one of placenta prævia, and one of rigid os—all of which terminated favorably.

This paper was discussed by Drs. Mitchell, of Cincinnati; H. A. Kelly, Earle, of Chicago; Barker, of Phila-

delphia, who condemned accouchement forcé except in certain rare cases, and thought it had cost many lives. Much was said about meddlesome midwifery, danger of sepsis from use of the finger, etc.

Suspensio Uteri.—Dr. Howard A. Kelly, of Baltimore, made some remarks based upon the principal points contained in a paper upon this subject. The board, drawings, and photographs were used in illustration. He claimed to be the originator in suspending the uterus by attaching it to the abdominal walls. He wrote a paper ten years ago upon the correction of retro-displacement of the uterus by stitching the organ to the anterior abdominal wall. It had since come to be one of the tested gynecological procedures. He and others had designated this method of keeping the uterus forward by several terms (hysterorrhaphy, ventral fixation, etc.), which he regarded as inappropriate, and he had come to call it suspensio uteri. The suspension of the uterus could be effected satisfactorily by two methods, and by only two. In the one, the abdomen being opened, sutures were passed through at the horns on both sides and fastened to the walls of the abdominal incision. In the other method the sutures passed entirely through the uterus at its base. He used silk and left it in. One would find that after several months the uterus could be moved freely, but could not be thrown backward. He had done other operations, among them shortening the round ligaments within the abdomen, but the uterus soon fell back.

It was not to be supposed that suspensio uteri should be practised in all cases of retro-displacement. At the dispensary of the Johns Hopkins their attending physician had sent up to him only eighty cases out of several hundred in which he thought this procedure was called for, or mechanical measures had failed. Dr. Kelly had operated on only 44 of the 80. The result, however, had been entirely satisfactory in all the 44. The women were of two classes, the unmarried, and the married who had all borne more than three children apiece. Of the 44 there had been 18 single, 23 married. Among other symptoms which had disappeared in many, were those of a hysterical or nervous nature.

Dr. H. J. Boldt, of New York, thought Dr. Kelly should not object to the term ventral fixation since he left in the silk ligature, for that would certainly keep the uterus fixed unless it cut through the walls. It was objectionable too, for it would interfere with the advance of pregnancy. Dr. Boldt claimed to have first denominated the operation suspension of the uterus. He would do the operation only where a pessary failed to keep the uterus up, or the patient was anxious to get rid of the pessary, or the abdomen were opened for some other condition. To open the abdomen for this operation when the uterus was quite movable, was unjustifiable. Alexander's operation was then indicated.

Lactational Insanity.—Dr. George H. Rohe, Superintendent of the Maryland Asylum for the Insane, read this paper. He said prolonged or excessive lactation had been given as the chief cause of insanity occurring during the nursing period. In most cases this was probably true, yet there were some in which the disease must be attributed to other etiological factors.

Recent careful study of insanity during the lying-in period had shown its frequent dependence upon septic puerperal processes. Certain of his own observations, presented at the last meeting, might be regarded as confirmatory of this view. In insanity the psychical phenomena were generally so striking as to overshadow bodily anomalies, and thus these had failed to be noticed.

Among the most recent authorities Dr. Bevan Lewis regarded the exhaustion and sequelæ of labor, and defective uterine involution, as important etiological factors, especially in the earlier cases of lactational insanity.

Seven and four-tenths per cent. of all the women admitted to the Maryland Hospital the past two years developed their insanity during the beginning of the nursing period. They were thus classified: Melancholia, 2; mania, 1; confusional insanity, 2. Of the latter two one died and the other went on to profound dementia. The case of mania was discharged, recovered, after six months. One of melancholia recovered after repairing a badly lacerated cervix. The other case had improved.

The average proportion of puerperal insanity in its widest sense to all insanities in women was about ten per cent. Among these the number of cases of lactational insanity number on an average thirty-five per cent.

The practical question of prognosis was hard to settle by the statistics.

The treatment of lactational insanity resolved itself simply into the exercise of the principles of general therapeutics: remove sources of irritation, correct aberrant functions, restore wasted strength. These principles, if consistently carried out, would usually lead to success.

The Abuse of Emmet's Operation for Laceration of the Cervix.—Dr. E. C. Dudley, of Chicago, read the paper. Emmet first operated for laceration of the cervix in 1862, and published his statement in 1869. He published elaborate papers in 1874 and 1877. Notwithstanding the clearness with which the indications and contra-indications, and the technique, were defined, the operation was still often so badly executed as to be followed by most disappointing, and sometimes by injurious, results. He passed by with mere mention the abuse of applying the operation to cases unsuited to it, including those in which the laceration was slight and not associated with uterine catarrh, cervical cystic degeneration, cervical erosion, and cervical eversion.

The most common faults in the execution of trachelorrhaphy, so that the operation might fail or do harm, were: 1, disregard by the operator of the presence of granular endometritis; 2, closure of the os externum so tightly as to obstruct the free outflow of secretions; 3, failure to remove cicatricial plug in the angle of the wound; 4, rolling the diseased cervical glands into the cervical canal, where they found expression either in cervical catarrh or retention cysts.

Granular endometritis furnished a positive indication for forcible dilatation and curettement, uterine irrigation, and the application of strong carbolic acid and iodine, all of which should immediately precede closure of the cervix except in aggravated cases, when the curettement should be followed by thorough and repeated uterine tamponade of gauze after the method popularized by Polk.

In practice he now found most cases requiring curettement for catarrh, and his results had been much better since adopting the custom of exploring in nearly all cases for this condition.

Effectual treatment of the diseased Nabothian glands pouring out large quantities of white-of-egg secretion required their removal by excision, cauterization or free use of the sharp curette was not sufficient.

Fourth Day, Friday, June 9th.

After-treatment in Cœliotomy.—Dr. Flemming, of Denver, read a paper on this subject. He did not hesitate to say emphatically that opium should not be given to control pain unless the patient had been addicted to the use of the drug. He believed opium had killed more patients than cœliotomy. It checked peristalsis, natural secretions, caused thirst, restlessness, etc. As to laxativeness, they gave small doses of calomel, or if this caused nausea they gave salines. Where drainage was employed it was either by glass tube or iodoform gauze. To prevent pain of tympanites they avoided opiates, kept up peristalsis by hot-water injections and the use of laxatives. The long rectal tube had been of little use in the majority of their cases. More benefit had come from hot-water injections. They gave ten grains of sulphate quinine twice, if necessary, in twenty-four hours.

Reopening the abdomen was practised under three conditions—hemorrhage, sepsis, and peritonitis—although their experience in this line had been limited.

Regarding diet, the less one put into the patient's

stomach the first forty eight hours the better. Then give fluid food, and if there were nausea give predigested food. After a few days almost any food desired could be given with exercise of due care.

Dr. Mitchell, of Cincinnati, regarded the subject matter of this paper as most important in gynecological practice. The success of cœliotomy depended upon the after-treatment. No food should be given in twenty-four or forty eight hours. The drainage tube also acted in controlling hemorrhage.

Dr. J. H. W. Chestnut, of Philadelphia, queried as to the theory of the drainage-tube controlling hemorrhage. The clinical fact was well recognized. Like the author, he believed opium had done much mischief, but he thought that with care it could be used with benefit in some cases not addicted to the opium habit.

Dr. Newman, of Chicago, said that in a hospital with which he was connected they used iodoform wicking in drainage instead of iodoform gauze. It did not become thready like gauze, and drained even better. They also applied the Esmarch bandage around the abdomen over the dressing, and had found it gave the patient comfort by its elastic support to the relaxed wall, and also by its warmth and soothing influence.

Memorials were presented for publication in the volume of the Section's Transactions of the late Dr. A. Reeves Jackson and Dr. F. M. Johnson.

A vote of thanks was tendered the Chairman, Dr. Duff.

SECTION ON SURGERY.

First Day, Tuesday, June 6th.

Antiquity of Syphilis.—Dr. J. T. Jelks, of Hot Springs, Ark., President of the Section, delivered the annual address, taking as his subject a consideration of the antiquity of syphilis. He congratulated the profession upon the advance of surgical methods in the past fifty years, especially through the introduction of anæsthetics, antisepsis, and modern bacteriology, which as yet is in its infancy. Some indeed affect to slur at the good work done in the days of our fathers as viewed by the light of modern research; but this spirit should receive no sympathy.

Referring to the subject of his paper, he said that Dr. Buret had proved that syphilis was known many centuries before the Christian era. In 1921 B.C., Abraham introduced his wife Sarah as his sister to the court of the Egyptian Pharaoh, who took her to wife, and as a consequence infected himself and all his other wives, so that the infection spread through the court and a plague of sterility followed. In the book of Psalms, King David graphically describes his sufferings due to his own transgression, and his description is a perfect representation of tertiary syphilis with iritis and gummata. Moses speaks of a severe epidemic among his men following upon their intimate relations with Moabitish women. To check it he ordered the massacre of twenty-four thousand tainted men, and later all the women who had known men carnally. The worship in the temples of Baal was simple prostitution, and the epidemic of Baal was undoubtedly syphilis, although possibly in a rather more acute form than it presents to-day, as the human race may now be partially inured to it through the sufferings of former generations.

Acute Intestinal Obstruction Treated by Laparotomy.—Dr. A. J. Ochsner, of Chicago, reported three cases of this nature. He regretted that he could not report a larger number, but offered them, knowing the value of individualization in such cases.

Case I.—A child, after a fall, had slight recurring pains in the abdomen. The pain increased gradually with the formation of a sausage-shaped tumor to the right of the umbilicus. Laparotomy in the middle line below the umbilicus showed an intussusception of the ileum into the cæcum which required considerable force to reduce. The appendix was removed, for it was very long and formed a complete loop around the ileum, and evidently was the cause of the trouble. The recovery was rapid and uneventful. The force necessary for the reduction of the intussusception proved that injections of water would have been useless in this case.

Case II.—A laborer, thirty-two years of age, complained of pain in the left inguinal region following a fall. Three days later the symptoms were nausea, tympanites, and obstipation, with an indistinct tumor in the left inguinal region. A diagnosis of volvulus was made. Laparotomy disclosed a volvulus of the sigmoid flexure. The twist was easily unturned outside of the abdomen, but the inflated intestine could only be returned after the withdrawal of gas through a large anal tube.

Case III.—A man, eighty-one years of age, had increasing umbilical pain, with shock and stercoraceous vomiting on the third day. A diagnosis of obstruction of the small intestine, cause unknown, was made. Laparotomy revealed a loop of intestine, one foot long, which had slipped under Meckel's diverticulum. It had evidently been there for years, but strangulation had occurred recently. Death followed from shock in thirteen hours. The author wished to call attention to the great value of washing out the stomach with a stomach-tube before operating upon cases of intestinal obstruction from any cause, especially if stercoraceous vomiting is present. It will lessen the vomiting during and after the operation, and so reduce shock as well as the inhalation of vomitus.

Unnecessary Restrictions in Surgery was the title of a paper read by Dr. J. D. Roberts, of Philadelphia. He pointed out the danger of too blindly following the dogmatic statements of many of the teachers of to day, and so of limiting the amount of good which comes from individual experience. He believed that the immobilization of fractures of a limb after operations, or in joint diseases, is often carried on too long simply from theoretical reasons. Water is denied to laparotomy patients too frequently, simply from the dictum of old teachings, certainly not from the result of individual experience. The restrictions in the after-treatment of operations upon the eye are too frequently severer than are necessary.

While the speaker did not advocate a reckless cutting loose from the old-established customs which govern all the details of the management of stated cases, still he wished to make a plea against the blind following of all the rules from memory, and not from the knowledge of their why and wherefore, and to protest against the old routine treatment without regard to the individuality of the cases.

Report of Cases in Evidence of the Surgical Impunity of the Peritoneal Viscera.—Dr. J. E. Link, of Terre Haute, Ind., presented a communication with this title. The author had recently made numerous intestinal sutures for artificial wounds and gut resections in dogs, without the slightest attempts at antisepsis or even cleanliness, and yet his results are uniformly good. He gave an exhibition of this "dirty surgery" upon the body of a dog, fearlessly cutting open the abdomen, inserting his unwashed hand into the peritoneal cavity, making a rough gut-resection, the ends loosely joined with three or four stitches, and the large abdominal wound closed with only a single stitch. He showed several specimens of former operations in which the gut had healed perfectly and no stenosis had resulted. He has found that the peritoneum can invariably care for any dirt or even small particles of fæces with impunity to itself, though the outer wound does not do as well as when asepsis is secured. He believed that what is true of the peritoneum of the dog is also true of that of man. His object in presenting these cases to the Society was not in any way to lessen the importance of asepsis and antisepsis in abdominal surgery, for he is a firm believer in them, but to encourage general practitioners to operate immediately in cases of emergency, such as perforating wounds of the intestine, even if their technique is not perfect, rather than to make the fatal mistake of delaying until a specialist can be summoned from many miles away.

The paper created a lively discussion, and inasmuch

as the canine peritoneum cannot be properly compared with the human peritoneum, the danger of such teaching, in tending to reduce carefulness in abdominal surgery, was clearly pointed out.

SECOND DAY, WEDNESDAY, JUNE 7TH.

Stricture of the Ureter.—DR. CHRISTIAN FENGER, of Chicago, described an operation for the relief of stricture of the ureter in cases of hydro- or pyo-nephrosis. Lumbar nephrectomy has a mortality of thirty-seven per cent., while nephrotomy, including twenty-two per cent. for the primary operation and seven per cent. for the secondary closing of the fistula, has only twenty-nine per cent. Still, nephrectomy is a single operation and cures immediately, if at all. But there are certain cases of hydro- or pyo-nephrosis where it is not indicated.

In many cases intermittent hydronephrosis is due to the oblique opening of the ureter into the pelvis of the kidney, which causes its closure until the pelvis is moderately distended, when there is a discharge of its contents. In these cases an incision can be made into the pelvis of the kidney through the usual lumbar incision, and the opening into the ureter can be made more patulous by simple plastic surgery. The author reported a successful case of such procedure.

Again, hydronephrosis from stricture of the ureter, due either to ureteritis or partial rupture from traumatism, can be successfully treated without a nephrectomy. If the stricture is a limited one, a short longitudinal incision can be made through the stricture, followed by the union of the opposite ends of the incision, so that the line of sutures is transverse although the incision was longitudinal. He reported a successful case of this operation. The upper two-thirds of the ureter can be reached through the lumbar nephrotomy incision extended downward if necessary; the lower third by making an osteoplastic flap of the sacrum.

Transverse union of a section of the ureter is rarely successful, and lateral anastomosis and other methods require an exceptional length of the ureter.

When possible, nephrectomy should be avoided, as frequently the hydro-nephrotic kidney retains remarkable secretive power and the soundness of the other kidney cannot be definitely ascertained. Therefore the operations indicated by the author are a step toward conservatism.

Operations on the Gall-tracts.—DR. J. B. MURPHY, of Chicago, read a paper on this subject. He called attention to the anatomical relations of the gall-bladder, recommending an incision over the ninth right costal cartilage in all operations upon that viscus. The single function of the gall-bladder is to control the tension of the gall circulation, and it is not necessary to life. In dogs after its removal he has observed the gradual distention of the cystic duct until it replaces the removed gall-bladder. Healthy bile is not septic; but bile which escapes pathologically into the peritoneal cavity is septic, owing to the pathological cause.

The author has collected 25 cases of simple surgical puncture of the gall-bladder for diagnosis, with a mortality of twenty-five per cent. Of 23 cases of simple incision and drainage, eighteen per cent. died. In 59 cases of primary suture of the gall-bladder to the abdominal wall and a secondary incision, the mortality was ten per cent., the lowest of all operations upon this viscus. In 201 cases of the same operation but done in one sitting, twenty-five per cent. died. In cases where all the bile drains outside the patients die of marasmus, and those operations which retain the flow of bile in its natural channel are far preferable. In cholecystotomy without drainage the mortality is twenty-three per cent.

The author strongly advises cholecysto-enterotomy, joining the gall-bladder to the intestine near the normal opening of the common duct. He has done this, using a button similar to his intestinal button many times in dogs, with universal success. He has operated in this manner seven times for encysted gall-stones in man, and his colleagues two more times, and all nine cases are living. In one operation for pancreatic cancer death resulted from causes not attributable to this method.

The author points out the dangers of protracted abdominal operations and the saving of valuable time by the use of his intestinal button.

He operated upon a living dog before the Section, completing the operation in about ten minutes.

Intestinal Anastomosis Without Plates.—DR. M. E. CONNELL, of Wauwatosa, Wis., described his improved method of securing intestinal anastomosis. Diagrams and specimens were shown to the meeting illustrative of the author's new method. This is a lateral anastomosis by means of longitudinal incisions into the sides of the intestine after the closure of the open ends. The method is new simply in the suturing employed, and consists of an uninterrupted through and through suture of the two adjoining sides of the incisions, but with the loops of each stitch left long enough to allow the intestines to be turned until the two further sides of the incisions can be approximated and then sewed by a tight continuous suture. The intestines are then turned back again, and the first suture is drawn tight until the loops have disappeared and the knots are secured. This method has proved very successful in operations upon dogs, and as it requires but a few minutes for its completion, its advantages over more complicated methods of suture are obvious.

A Case of Chronic Glanders, with Recovery was reported by DR. BAYARD HOLMES, of Chicago. Glanders is rare in man, and presents itself in one of two forms, either an acute affection fatal in the course of a few weeks, or else a distinctly chronic disease. The author presented a patient, a farm hand, twenty-six years of age, who, four years ago, after caring for a horse suffering from glanders, was attacked by multiple abscesses. These were very radically treated by operation and their contents were used for inoculation experiments upon rabbits and guinea-pigs, with the result of death in the rabbits and orchitis in the guinea-pigs. For two and one-half years the patient was subjected to operation twenty times, either for the elimination of new foci or the recleaning of the old ones. The wounds all healed slowly. The patient is now entirely well.

A New Operation for Varicose Veins was described by DR. ERNEST LAPLACE, of Philadelphia. As the varicose veins are aneurismal in character the treatment can rightly be compared to that of aneurism.

Radical measures are usually limited to acupressure, ligature, or excision. The measures employed to cause coagulation are too painful and too limited in the extent of their action.

The long saphena drains the front of the leg and the circumference of the thigh, and the short saphena drains the posterior surface of the leg. The author's method is to ligate both veins, the long saphena at the saphenous opening and the short one just below the popliteal space. Elevation of the limb and rest in bed for a fortnight is the after-treatment. The author has done the operation seventeen times with perfect success, with the exception of one case in which there was an anomalous position of the long saphenous.

The advantages of the operation are that it can control very extensive varicose veins, that it can be done easily with cocaine, and that no relapses have occurred.

DR. R. M. RICKETTS, of Cincinnati, presented some specimens and a diagram illustrating the method of the Mansell operation of intestinal anastomosis.

Partial Amputations of the Foot.—DR. T. H. MANLY, of New York, read a paper on this subject. In spite of the fact that instrument-makers say that partial amputations of the foot yield results less satisfactory than amputation of the leg at the point of election with the application of an artificial leg, the author wished to uphold the old principle of the preservation of healthy structures as far as possible. The more he sees of lacerations of the feet the more doubtful tissue he spares. Al-

though the result of the tarsal amputations is not always satisfactory, an amputation of the leg later can always be resorted to if necessary. Nor is the artificial limb so invariably satisfactory as it is often represented. It necessitates time, care, and expense, and not infrequently causes trouble in the stump.

Appendicitis.—Dr. Jos. Hoffman, of Philadelphia, presented a communication on inflammation of the appendix. The author reviewed the various anatomical positions of the appendix, which account for the variety of the places to which the pain is referred and the difficulty of finding the appendix in some operations. To arrive at a diagnosis in doubtful cases the moderate use of salines and calomel is of great value. The aspirating needle should never be used, an exploratory incision being much safer. Operation should not be delayed in those cases which do not do well, and should be immediately employed when any evidence of suppuration is present.

Regarding the operation between attacks, the author advises operation after even the first well-authenticated attack of appendicitis, to prevent any chance of a recurrence.

Extirpation of Aneurisms.—Dr. Joseph Ransohoff, of Cincinnati, read a paper with this title. The operative methods of treating aneurisms are the Hunterian proximal ligation, the splitting of the aneurismal sac with ligation above and below, and lastly the total extirpation of the aneurism.

The disadvantages of the first method are its high rate of mortality, about eighteen per cent., the frequent recurrence of the aneurism even after the lapse of years, and the frequency of gangrene and secondary hemorrhages.

In the second method the sac is left behind and is practically a foreign body, often giving rise to suppuration. The mortality is eleven per cent.

Total extirpation is an operation devised centuries ago, and has been revived within the past few years. It is an ideal operation upon aneurisms of the smaller vessels, and its results are just as perfect upon the large vessels of the extremities. The author has collected forty-six cases of this operation, more than half being upon the large vessels, with only one death in a case of aneurism of the scalp. In none of the cases did secondary hemorrhage, gangrene, or a relapse occur. He reported two cases of his own resulting in perfect cure of radial aneurism.

A New Operation for Anterior Cleft-palate Combined with Harelip.—Dr. John Wyeth, of New York, described his method in a short paper supplemented by a series of diagrams. Silver wire is inserted at about a quarter of an inch from the anterior edges of the gaping bones, and the alveolar process of the most affected side is chiselled through at about the middle point. The wire is then drawn taut, and the freed portion of the alveolar process is thus brought to join the opposite maxilla at the front of the mouth. Union is secured in from six to eight weeks, and then the plastic work upon the lip and nasal alæ is undertaken according to the usual plan. The advantage of the new method is that bony support is secured in the front of the mouth, and therefore the cosmetic results are far better than usual in severe cases.

The author advised early operation, always in the first year of life, and preferably in the first three months if the general nutrition is good.

Third Day, Thursday, June 8th.

Brain Surgery.—A paper on this subject was read by Dr. F. C. Schaefer, of Chicago. The author reported nine interesting cases of injury to the head. The diagnosis of intracranial lesions of traumatic origin is still uncertain, and every carefully reported case is of value. He showed his method of controlling hemorrhage from the scalp incision. He winds a solid rubber tubing around the head two or three times in the diameter of the occipital protuberance and the frontal sinus, and ties it securely. This tourniquet is held in place by three silk stitches taken in the scalp.

The author advises against delay in operation in any case where there are doubtful symptoms, as an incision through the scalp is not dangerous and may lead to the discovery of important conditions necessitating immediate further interference.

Treatment of Empyema.—Dr. E. L. Shurley, of Detroit, read a paper entitled "Artificial Opening of Pulmonary Cavities, Insertion of Rubber Tube, and Injection of Chlorine Gas."

Pulmonary cavities have been opened surgically as early as 1844, but the general result has not been very satisfactory. The diagnosis of the nature of the cavity is not always easy, nor is the exact localization of the cavity, whether deep or superficial. Cutting through sound lung-tissue to reach the cavity has both immediate and remote dangers.

The author has demonstrated the valuable effects of chlorine gas in destroying tuberculous and suppurative bacilli. As the direct inhalation of a sufficient quantity of chlorine gas is impossible, the author advocates the opening of the cavity from the lateral chest-wall, the insertion of a rubber tube, and the pumping of the chlorine gas mixed with air through the tube. He uses a bottle half full of chlorine water and pumps the air through the bottle into the tube, the air carrying with it a sufficient quantity of the gas. No coughing ensues, as the irritant does not reach the larynx.

In a case of pneumo-pyothorax in which this method was tried the result was satisfactory, though a fistula remained in the course of the drainage tube.

In two other cases of operation on tubercular cavities the patients ultimately died, though the immediate effects of the operation were beneficial. The author does not believe in the universal tubercular nature of empyema, and therefore thinks that the field for this operation is a large one. He advocates the use of gas rather than of fluids in the thoracic cavities.

Dr. J. McFadden Gaston, of Atlanta, Ga., also presented a communication on thoracic surgery. He reviewed the advance made in thoracic surgery in the past years and ended his paper with a summary. All penetrating wounds of the thorax should be closed hermetically after the oozing of blood has ceased. If severe hemorrhage is present efforts may be made to check it by operation. The use of the probe should be given up. Foreign bodies in the bronchi should be removed by means of a low tracheotomy and the introduction of forceps.

Reaching the bronchus from the lateral chest-wall is a dangerous procedure, and the localization of the foreign body is very difficult.

In serous pleurisy drugs and expectant methods should be employed at first, aspiration should be resorted to in cases of large effusion or in delayed absorption.

Eslander's and Schede's operations are not regarded so favorably as formerly. Partial resection of the ribs is better than either, except in cases of large persistent abscesses, or gangrene of the lung.

In empyema partial resection of one rib with large drainage-tubes is usually the best operation. Washing out the pleural cavity is usually not necessary.

In gangrene of the lung, thorough opening with considerable gauze-packing, is most satisfactory.

Tumors of the mediastinum are much more frequent at autopsy than on the operating-table.

Resection of portions of the lung has not been performed often enough to draw any satisfactory conclusions from it.

In the discussion of the paper, Dr. LaPlace, of Philadelphia, ably pointed out the advantages of gauze-packing over a drainage-tube of any kind. The former is thorough complete drainage by capillary attraction, the latter is often no drainage at all, simply a useless foreign body.

Election of Officers.—The following officers of the Section were elected for the ensuing year:

Chairman, J. B. Roberts, of Philadelphia; *Vice-Chairman*, J. D. Griffiths, of Kansas City; *Secretary*, F. W. McRea, of Georgia.

(To be continued.)

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Twenty-seventh Annual Meeting, held at Asbury Park, June 27 and 28, 1893.

GEORGE T. WELCH, M.D., OF PASSAIC, PRESIDENT.

Address of Welcome.—DR. SAMUEL JOHNSON, Chairman of the Committee on Arrangements, read a brief address of welcome to Asbury Park. He said it had been four years since the Society had met here before, during which time many improvements had been made. The town had all the essentials of health. There was a custom among the Greeks and Persians of giving to the victor water and earth. "To-day," he said, "we tender you the ocean; you can have the earth if you want it."

The Secretary, DR. WILLIAM PIERSON, then read an abstract of the minutes of the last annual meeting; after which Dr. William Perry Watson, recognizing the presence of the Honorable James A. Bradley, moved that he be invited to a seat on the platform.

MR. BRADLEY said it was an honor to any town to be visited by the New Jersey Medical Society, and he asked the favor of the Society to sit for a photograph, as he would like to have it to adorn a room which he was preparing for the reception of bathers who might become exhausted in the water. He would also like the privilege of presenting a copy of the picture to each member. Mr. Bradley's generous proposition was accepted.

Permanent Delegates.—The following named gentlemen, having been recommended by their district societies, were elected permanent delegates: Drs. Alonzo Pettit, E. B. Silvers, P. A. Harris, G. E. Redding, and B. A. Waddington.

Jealous of Its Surplus.—DR. E. J. ILL offered a resolution authorizing the appropriation from the accumulated funds of the Society of a sum sufficient to cover the initiation fee and first assessment to make each member of the district societies also a member of the Society for the Relief of Widows and Orphans of Medical Men. The funds in the treasury now amount to over five thousand dollars, and the discussion last year and at this meeting showed some feeling against the use of this money for any other purpose than that for which it had been collected—the legitimate expenses of the State Society. Under a recent by-law Dr. Ill's motion had to lie over one year.

Honorary Members.—DR. H. G. TAYLOR, Chairman of the Committee on Honorary Membership, said that no new names had been presented during the year, but that last year the Committee had reported favorably on the names of Drs. F. S. Dennis, John H. Ripley, and Virgil P. Gibney, of New York, and under the by-laws the election had been deferred until the present meeting. One member wished to know whether a committee had not been appointed to ascertain whether all these gentlemen were members of the American Medical Association; and as it appeared no committee had been appointed for that purpose, the balloting was proceeded with, and Drs. Dennis, Ripley, and Gibney were duly elected honorary members.

The Health of New Jersey.—DR. D. C. ENGLISH read the report of the Standing Committee of which he was chairman. In it was given a summary of the health of New Jersey, ascertained, as usual, by blanks sent to members of district societies. There had been unusual exemption from zymotic diseases. Improved sanitary conditions had been reported from most counties, attributable largely to the expected visitation of cholera. There had been considerable variola at Red Bank. An epidemic of hysteria had been reported from Cramer Hill, due to religious excitement, in which both men and women were affected. The hospitals and charitable institutions reported a decided increase of work over preceding years, which Dr. English said demonstrated that New Jersey compared favorably with her sister States in open-handed charity. But the reporter from Camden County had questioned whether their charity was not greatly abused. In the matter of treatment, one reporter practised in scarlet fever washing the entire body with a solution of corrosive sublimate; another recommended large doses of calomel, in pneumonia, repeating, if necessary, until two grains had been used.

In Essex County a number of the physicians had entered a movement to supply families who wished it with disinfected milk, and it was thought that if it should prove practical it would be well to extend the movement to other parts of the State.

The Committee questioned the propriety of continuing these reports, as they practically duplicated the work in this direction of the State Sanitary Association. That portion of the report containing suggestions in case cholera should visit us was, on motion of Dr. Godfrey, ordered printed in pamphlet form for distribution.

Bovine Tuberculosis. Its Transmission to Man, and How to Prevent It.—DR. J. W. STICKLER, of Orange, read the paper. The history of tubercles as found in the bovine species did not differ, so far as he could learn, from that of tubercles found in man. The bovine tribe was pre-eminently disposed—equally so with man. He quoted the statement that no predisposing cause exercised such a potent influence in the production of tubercles as heredity. Breeding in-and-in predisposed. Alderneys, Guernseys, and short-horns were especially prone to the disease in Scotland, and Jerseys in this country. Early, late, and over-breeding predisposed. Animals with light barrels, narrow chests, and disproportionately long legs were more apt to have tuberculosis than those perfectly formed. Climate, locality, debility, had a potent influence. Serous membranes were oftenest affected; next came the lungs. Some general points in pathology and symptomatology were considered.

In answering the question whether human and bovine tuberculosis were the same, he would say that when lower animals were inoculated with tuberculous matter from man the results were the same as when tubercular matter from the lower animals was used, and in each case the tubercle bacilli were found.

Anatomically bovine tuberculosis was a progressively advancing affection in which nodes and nodules were found. These might be single or aggregated. Calcification was more common than caseation.

Lower animals fed and inoculated with matter from such nodules got tuberculosis (Gerlach, Creighton, Orth, etc.). Bollinger produced tuberculosis in pigs by feeding them on milk from tuberculous cows.

The question, was bovine tuberculosis communicable to man could, the author thought, be satisfactorily answered in the affirmative. Klebs, Bollinger, Stein, Johns, Bang, Toussaint, Cheveau, and many others besides Koch, concurred in stating that if milk from cattle with tuberculous udders were given for a lengthened period, tuberculosis would develop.

Professor Thomas Walley, of Edinburgh, wrote him that he had himself been inoculated three times in wounds received while dressing tuberculous carcases, and had lost a child from intestinal tuberculosis in which all the evidence pointed to infection through milk from a tuberculous cow. The letter stated further that there was not a pathologist of note in Europe who denied the identity of human and bovine tuberculosis. It was accepted at the Hygenic Congress in London as an established fact. A similar view was expressed in a letter received from Dr. J. C. Corlies which further quoted Nocard, member of the French Academy of Medicine, on steps taken to prevent spread of tuberculosis among men from cows in Paris. The rules were carried out by veterinarians. Tuberculin was recommended in diagnosis by Corlies.

To prevent spread of tuberculosis from cattle to men was a question considered in letters received from Von Hebra, of Vienna; Walley, of Edinburgh; Duffield, of Michigan; Frank S. Billings, and others. Billings' communication was of considerable length, and stated that there was little tuberculosis in cattle on the prairies; that meat was not dangerous when there were few tuber-

cular foci, especially when well cooked. The danger was greater in milk, especially for the young, but was much diminished by feeding the children with mixed dairy milk, and not milk from one cow. He recommended locating every dairy in the State, have a laboratory and working forces, inoculate cows with tuberculin, if there was a reaction let the owner sell or fatten them, but when the cattle were slaughtered it should be under inspection of a veterinarian.

The paper was discussed by Drs. W. B. E. Miller, Corlies, Baldwin, Rogers, Laur, Coit, Charles Young, Benjamin, Lielbach, C. E. Redding, and the author. A resolution was adopted which called for the appointment of a committee to co-operate with committees from certain other societies, to secure legislation against the spread of bovine tuberculosis. Later, the President appointed Drs. Stickler, A. W. Baldwin, and Charles Young.

Voice Regained after Total Extirpation of Larynx and Vocal Cords.—Dr. H. S. Wetherill, through the courtesy of Dr. Delavan, exhibited the man on whom Dr. Solis-Cohen had completely extirpated the larynx, with the vocal cords, and who had nevertheless regained his voice so that he was able to talk distinctly in a whisper. A tracheotomy tube was worn just above the sternum. It was the only case of the kind on record.

The President's Annual Address.—Dr. George T. Welch, of Passaic, chose for the subject of his address, "Therapeutical Superstition" (see p. 33).

Legislation for the Prevention of Blindness.—Dr. W. B. Johnson, of Paterson, read this paper. The necessity for legislation to prevent the increase of blindness was shown by the fact that the ratio of increase of blindness in the State was greater than that of increase of population, and also by the fact that blindness was, in large measure, a preventable condition. The question had received attention in other countries, and laws had been passed, and in our own country New York State had set a laudable example. Dr. Johnson quoted Cornelius Agnew, C. J. Kipp, Lucien Howe, resolutions adopted by the American Ophthalmological Society, the law of the State of New York, etc., to show that if midwives were to report early any cases of eye trouble, if physicians were to adopt proper treatment at once, if the public could have rules to govern them in avoiding contagious ophthalmia; if, in short, suitable legislation were enacted, much could be done to prevent the increase or occurrence of blindness.

On motion of Dr. Harris, of Paterson, the President was authorized to appoint a committee of three to consider the question of legislation to prevent blindness, and to report at the next annual meeting. The President appointed Drs. W. B. Johnson, C. J. Kipp, and P. A. Harris.

Delegates from State societies handed in their credentials, Dr. Walter B. Chase appearing from New York and Dr. W. B. Johnson reporting from the American Medical Association. Later a resolution was adopted intended to elicit the opinion of the profession in the State regarding the Code of Ethics as requested by the American Medical Association.

Modern Methods of Venders of Drugs.—At the last annual meeting the subject presented for discussion on this occasion was entitled, "Is the Philosophical Practice of Medicine not Materially Jeopardized by the Modern Methods of Venders of Drugs?"

The discussion was opened by Dr. H. L. Coit, who took the ground that the philosophical practice of medicine was jeopardized by venders for two or more reasons: first, the vender's purpose was wholly commercial; second, the materials which they dispensed consisted for the most part of substances which were entirely worthless to the profession. But there were three classes of tradesmen in drugs: one included the scientific pharmacist whose motives were above question, whose services had proved invaluable in getting out the new pharmacopœia, etc.: the second included the unvarnished charlatan; the third the pseudo-scientific manufacturer and vender.

Dr. Stickler said he did not see how we could be any more affected by the venders of drugs than the principles of Christianity could be affected by the teachings of Professor Briggs. There was some further discussion by Drs. Rogers, Redding, Alexander, Marcy, and Andrews.

Quarantine of Cholera.—Dr. William Elmer, Jr., third vice-president, read a brief essay in which he presented the present status of quarantine against cholera in this country, and while regarding present arrangements as superior to any existing heretofore, expressed the opinion that there should be a national board of health with a national bureau. He said his views were quite in accord with those expressed by Dr. T. Mitchell Prudden in a recent article in a popular magazine, in which a central bureau of health was advocated. Such a bureau should be in close touch with State boards of health. He thought the time would also come when there would be an international quarantine service, and this should turn its attention to cholera at its origin, in the Ganges, wiping it from the face of the earth.

Some remarks on the paper were made by Drs. Kipp, Godfrey, and Mitchell.

Some Thoughts on Symptoms and Diagnosis.—Dr. S. E. Armstrong read the paper, reciting briefly a few cases in illustration of his views. Symptoms were certain manifestations indicating a deviation from the normal health, and in classifying his subject he made the following startling points for his deductions: 1. From pathological changes to symptoms, to diagnosis, to treatment. 2. From functional disturbances to symptoms, to diagnosis, to treatment. 3. From a lying and deceitful patient, a perfectly normal body, to an absence of rational symptoms, to a diagnosis, to treatment. 4. Anomalous cases.

Incidentally the author expressed the view that the faculties of the mind calculated to make a diagnostician and physician were, in general, best developed by a study of botany, logic, mental philosophy, and higher mathematics.

Case of Supra-vaginal Hysterectomy for Fibromata of the Uterus.—Dr. H. G. Wetherill presented a specimen and read the history of a case of supra-vaginal hysterectomy with extra-abdominal (Tait's) treatment of the pedicle for a large nodulated fibroid weighing fourteen pounds and a half, the patient having been refused an operation three years before by a Philadelphia surgeon. after opening the abdomen and discovering, as he said, extensive adhesions. Dr. Wetherill found no adhesions, and the operation was a simple one, although the shortness of the pedicle caused some difficulty. The patient had some rise of temperature, but made a good recovery. He thought Baer's operation might yet establish for itself the first place.

The proposed amendment to the By-Laws, extending the Treasurer's term of office from one year to five, was lost.

Officers were elected as follows: *President*, Dr. John G. Ryerson; *First Vice-President*, O. H. Sproul; *Second Vice-President*, William Elmer, Jr.; *Third Vice-President*, T. J. Smith; *Corresponding Secretary*, E. L. B. Godfrey; *Recording Secretary*, William Pierson; *Treasurer*, Archibald Mercer; *Standing Committee*, D. C. English, H. W. Elmer, and W. H. Izard.

Place of next meeting, Lake Hopatcong; time, fourth Tuesday in June.

In making its report the Nominating Committee said that Dr. William Pierson had shown his modesty in rejecting the nomination to Third Vice-President, the Vice-Presidents being regularly advanced until made President, and a vote of thanks was tendered him for his long service, twenty-six years, as Secretary. His name was also proposed as honorary member of the Society, to be voted upon at the next annual meeting.

Self-seeking Homœopathists.—Dr. Benjamin moved the appointment of a committee on legislation, and showed that at the last session of the Legislature the ho-

mœopathists had had a bill passed which would have excluded all other physicians from the State Hospitals for the insane had the Governor either signed or vetoed it.

The president appointed on the committee Drs. Ward, Sheppard, and Elmer.

Adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

HOSPITAL SUNDAY—MEDICAL OFFICERS OF HEALTH, THEIR RELATIONS TO PRACTITIONERS—THE EASTBOURNE CASE—THE PRESSURE ON THE HOSPITALS FOR INFECTIOUS DISEASES—DEATH CERTIFICATION—PIT BURIAL—NEW FELLOWS OF THE ROYAL SOCIETY—HONORS ON THE QUEEN'S BIRTHDAY—CONCLUSION OF SESSION AT THE ROYAL MEDICAL AND CHIRURGICAL SOCIETY—ATROPINE FOR CHOLERA—CAVENDISH LECTURE—RENAL SURGERY—WESTMINSTER HOSPITAL MEDICAL SCHOOL—VACANCIES—SMALL-POX DECREASING.

London, June 10, 1893.

To-morrow is Hospital Sunday in London, when collections are made in aid of these charities at most of the churches and chapels. In anticipation of the event a special supplement to *The Lancet* has been separately printed and distributed to the officials of the various places of worship. Such a supplement has now been issued for several successive years. The present issue contains an interesting sketch of the origin of the several hospital systems which are at work in the metropolis. The sketch contains some quaint quotations from early documents and is calculated to awake an intelligent interest in our medical charities.

Some medical officers of health seem to possess superabundant zeal, which would be all the better if tempered by discretion. They have received the support and confidence of the profession, but in too many cases have returned evil for good. Every now and then practitioners complain of the interference of these officers, who seem to think themselves entitled to question the diagnosis and comment on the treatment of cases, and otherwise make themselves obnoxious. In the exercise of their rights, too, many seem to be devoid of tact. I lately met with one instance where the officer ordered the drains at once to be taken up and relaid in a house where the tenant lay in an almost dying state, the reason being that there had been a communication between the sink and that of the adjoining house and it was desirable to examine the two at the same time. If every pair of villas were to be redrained for such a reason there would soon be an agitation against sanitary movements. But in this case the illness of the tenant was surely sufficient reason for delay, as no annoyance had been found from smells, etc.

Some time ago a cleric told me he was an antivaccinationist because he foresaw that health officers would become tyrants and all tyranny was bad. At times I have feared he had some ground for his fear. A very flagrant case has occurred at Eastbourne, a favorite sea-side resort. There a boy in the sanatorium, at the end of the thirteenth week of scarlatina, was removed to his home under the superintendence of the family adviser, who was supported by two other qualified practitioners in the opinion that to do so was safe, all desquamation having ceased. Nevertheless, the medical officer of health set up his own opinion against these three gentlemen, and actually induced his Board to take out a summons against the one who removed the lad. The excuse for this is that the Board were bound to support the opinion of their own salaried officer. This officer is a young man who has gone direct into the sanitary service on the strength of his diplomas, and has, therefore, no experience of medical practice, and apparently very little regard for the feelings or respect for the views of older men who are not official sanitarians. The case has given rise to some altercation in the journals, but I have not met a single member of the profession in London who has a word to say in defence of the indiscretion of the officer of health. If such monstrous doings should become common the sanitary service of the country would be in danger of being disorganized. Officers of health must be taught that they cannot be suffered to ride roughshod over their brethren. They must either observe the amenities required of other members of the profession or they must be ostracized. In the latter case they would soon be removed, for it is certain that the public would not consent for people to be imprisoned in sanatoria when their family attendants declared there was no necessity for such a course. It is said the Sanitary Board of Eastbourne is chuckling at the success of its vindication of its own importance. The town may sing a different song when it learns how many physicians have decided to recommend their patients to avoid that resort until it becomes clear that in case of contracting disease there they will not be imprisoned in the sanatorium, at the discretion of a medical officer, for a period which their own advisers consider unnecessary. I hear, too, that vaccination has been greatly neglected in Eastbourne. The local authorities had better mend their ways if they wish their town to retain its position as a health-resort.

The provision of hospital accommodation for infectious diseases is entrusted to the Asylums Board, which has for many years discharged its duties most efficiently. The Board has, however, found it difficult to secure sites for new hospitals, and the pressure of late has been such that, if continued, new hospitals must be built or patients cannot be provided with accommodation. Not unnaturally, the inhabitants of any locality object to a large hospital for infectious diseases being erected among them, and the Board seems to have been very unfortunate in selecting sites which have aroused opposition. The question of distance is no doubt important, and yet there are numerous localities where there is little room for objection. The Board has, however, been so frustrated that the matter has been mentioned in Parliament, and will, perhaps, obtain more attention.

Some shocking revelations have been made before the Select Committee of the House of Commons on Death Certification. It has been shown that pit burial is rather frequent in London cemeteries, and during the epidemic of influenza some pits were kept open for days, and even weeks, from twenty to forty bodies being placed in them. We affect to be utterly shocked at the common "fosse" of France and Italy, and yet there has been growing up among us a system that only differs in degree. It is well that a parliamentary committee should have been informed of the facts. We may hope for a thorough reform of our system of death certification from these revelations.

Among the new Fellows of the Royal Society are Dr. Gairdner, Dr. Alfred Russell Wallace, Professor Cossar Ewart, Dr. C. S. Sherrington, and Professor Trail.

The Queen's birthday was as usual marked by a distribution of honors in which the profession was not quite forgotten. The distinction of C.B. was conferred on several surgeons holding official positions in India and the colonies. At home a baronetcy has been given to Dr. C. Cameron, M.P., who, although he has given up practice for politics is useful as a medical member of Parliament. A knighthood has been conferred on Dr. O. Priestley, the eminent gynecologist and consulting physician of King's College, and also on Dr. Benjamin W. Richardson, whose sanitary and scientific work is well known. Some of his temperance friends have suggested that the honor is due to his advocacy of abstinence; I reply in that case the ministry have neutralized it by gazetting also an advertising wine merchant.

London, June 17, 1893.

The concluding meeting for this session of the Royal Medical and Chirurgical Society was held on Tuesday last, the 13th inst., when Dr. L. Brunton, whose tendency to theoretical therapeutics is well known, read a paper

on atropine in cholera. The idea results from the antagonism observed between atropine and muscarine. There is a similarity of symptoms between cholera and muscarine poisoning. A few months ago Dr. Brunton had an opportunity of testing the drug on a patient who came from Hamburg. A man and his child were admitted to the hospital; the man soon after died and the child was collapsed, but a subcutaneous injection of atropine revived her for a time. Then she relapsed, and the injection was repeated and the child recovered. There were never any rice-water stools in father or child, but Dr. Klein found comma bacilli in the intestine of the man. Dr. Brunton suggested that there were different forms of cholera and that atropine might be useful when cholera had most effect on the circulation, but not when the intestines were chiefly concerned; as in experiments with Dr. Pye-Smith the intestinal secretion was not arrested by atropine.

Brigade surgeon Scriven, from an Indian experience of twenty-eight years, could only recognize one form of cholera and rice-water evacuation as the most constant and characteristic symptom. Dr. Pye-Smith regarded the finding of the bacillus as a good diagnostic mark, whether it was the cause or not. He would not rely on any one symptom as pathognomonic. Colorless fæces only resulted from all the contents being washed away and the removal of succus entericus as secreted.

Dr. Patterson, who has seen cholera in Chili, said he saw the man before admission to the hospital and he had typical cholera. There were rice-water evacuations, temperature 96.6° F., pulse 110, blueness and suppression of urine. The child when he saw it had premonitory diarrhœa only. Dr. Ormerod, who made the post-mortem on the man, said the face was shrivelled, the blood tarry, the internal organs shrunken and light in weight, the intestinal contents colored. He contrasted the case with that of another man who had died of violent diarrhœa. In this there was no shrivelling, the blood was liquid, and comma bacilli were not found.

Some may perhaps be encouraged to try atropine further, but it seems to me that the case affords no expectation that it can be of any use except as a stimulant to the circulatory and respiratory centres, just as in any condition in which these centres are failing. It clearly cannot act as an astringent on the intestinal membrane.

A case of malignant disease (encephaloid sarcoma) of the thyroid was related in which the growth penetrated the trachea and displayed a tendency to become pedunculated.

The Cavendish lecture was delivered on Monday by Mr. Henry Morris, who took for subject some changes in surgical opinion regarding diseases of the urinary organs. Since Lawrence congratulated his class that the "kidney was fortunately beyond the reach of the surgeon," the changes in opinion and practice have indeed been great. To surgeons of our day the kidney is easily accessible, and is not only removed when too much diseased to be useful, but is subjected to other operative procedures. Mr. Morris has had no little experience and success in this branch of surgery, and his views are regarded with respect by other surgeons. His remarks on "Movable Kidney and Its Diagnosis" were very interesting, especially as to the necessity of distinguishing the condition from distended gall-bladder, floating spleen, and ovarian or other cysts which discharge their contents at intervals. But movable kidney is, he says, the most frequent cause of "phantom tumors." Mr. Morris divided surgical anuria, if I may use the term, into mechanical and reflex. The former occurs after nephrectomy or after destruction of one kidney by disease; through blocking of the ureter of the other side by clot, calculus, or muco-pus; through sinking of ureter of a movable kidney, or from pressure on ureter.

Reflex anuria is sometimes attributed to urethral irritation, but since the advance of renal surgery we know that mechanical irritation of one kidney may cause total suppression in both. Mr. Morris has quite given up probing with a needle for calculus and employs incisions in the curved border of the organ so as to introduce the finger. To do this satisfactorily the organ must be brought out to the surface of the loin where its structure can be examined by the eye while its interior recesses are completely explored by the finger. The remainder of the lecture was devoted to the mutations of opinion on the surgery of the bladder and urethra.

The Westminster Hospital Medical School has been long established and has certain advantages of position, but has never been successful. It still remains the smallest school, and many think it could be very well spared. If it were amalgamated with one of the other smaller schools it would diminish their number—perhaps to the general advantage. I mention this because at the present time there are a considerable number of vacancies, and judging from the many who in the past have joined the institution and speedily retired the attractions of these offices must be very slight. I hear it whispered, too, that the main cause of dissatisfaction is the want of a loyal management. When a first-rate teacher is obtained he is not retained—in fact, jealousies are permitted to interfere with him. Whether this is so or not we may take it for tolerably certain that someone is wanting in the *suaviter in modo* so necessary in such an institution. Dr. Grigg, who for nearly twenty years has been assistant obstetric physician to the hospital, has just resigned; so has Dr. Hughes Bennett. Dr. Sturges, the senior physician, also resigns the chair of medicine, and Dr. P. S. Abraham that of physiology. The last named is a specially heavy loss to the school. Dr. Murrell gives up Materia Medica, but retains therapeutics. Mr. Macnamara resigns surgery, and Mr. R. Davy operative surgery. There would thus appear chances for some of our young men, but I would warn them to look at the past history of this our smallest school, and to pitch their expectations of promotion, if successful, at several points below zero.

I am glad to report a decrease in the prevalence of small-pox. Influenza and diseases of the respiratory organs have greatly diminished during the prolonged fine and hot weather which has amounted to drought.

THE CHAMBERS STREET HOSPITAL.

To the Editor of the Medical Record.

Sir: The announcement has recently been made that the Society of the New York Hospital is about to erect new buildings for its down-town department. All who are familiar with the character of the work which it has carried on in Chambers Street must appreciate the necessity for enlarged room for the accommodation of the patients.

The new building will doubtless be spacious, modern, and well appointed, but the older ex-internes will always look back with very much pleasure on the work done in the small, inadequate building known as the "Chambers Street Hospital." Reference is made more particularly to the period between 1876 and 1888, during which time it was under the direction of Dr. William T. Bull. When Dr. Bull took charge of the hospital in 1876 he was fresh from his European studies, and imbued with the truth and importance of the then novel theory of antisepsis in surgery. Here the details of antisepsis, in its early days of carbolic acid and the cumbersome Lister dressing, were so carefully studied and thoroughly carried out, that we may say, without exaggeration, that the hospital was in the very front rank of continuous progress in the matter of wound treatment.

The house officers were imbued with the attending surgeon's thoroughness and attention to detail, and each department became the seat of active and energetic work. An idea of the relative increase in the size of the service may be gathered from the statement that, during the above-mentioned period, the ambulance service grew from nine hundred to twenty-five hundred calls, the out-patients from five thousand to nineteen thousand.

In the treatment of fractures, the reduction of dislocations by manipulation, the value of saline infusion, the management of wounds, and in fact in all branches of traumatic surgery, constant progress was made.

It was here that Dr. Bull, in 1884, successfully did laparotomy for gunshot wound of the intestine, and laid down principles which have since been generally adopted, and which have materially lowered the death-rate attending this formidable lesion.

As has been said, the house-staff and out-patient assistants worked with enthusiasm, they pointed with pride to the statement that patients admitted to other hospitals or dispensaries could be recognized as having come from Chambers Street by the excellence of their dressings.

It was not the intention of the writer to discuss these matters in detail, but simply to call attention to the fact that this small hospital in Chambers Street, soon to be demolished, has contributed not a little to modern surgery, and that it and its work will be affectionately remembered by the old house officers.

An Ex-Interne.

APPENDICITIS AND RATIONAL SURGERY.

To the Editor of the Medical Record.

Sir: In the Record of May 27th you chronicle the important fact that the appendix pendulum is beginning to swing the other way. These were glad tidings to all who have rational methods of dealing with pathological conditions at heart. Will you permit me to put in a mild protest against the spirit of your concluding remarks? If, as you say, conservatism in surgery is worthy of, at least, consideration, it still stands convicted, even though under extenuating circumstances.

Conservatism placed its indelible stamp upon the art of surgery with the advent of Listerism, when saw and scalpel gave way to drainage-tube and protective dressing, when limb preservation largely superseded limb amputation. Has anything occurred since that would justify its being defiled as half-brother to mental stagnation? I think not, but I think that the odium attached to it has been forced upon us by that coterie of men who wave the banner of radicalism on the floor of our professional gatherings and in the columns of our journals. Utterly possessed with the fervor operandi, they are blissfully ignorant of the fact that their teachings are evanescent and ephemeral, doomed to arouse wondering curiosity in the minds of generations that are to be. Radicalism subserves one good purpose: it sharply outlines our limitations, and after having fulfilled its mission it will yield the palm to rational surgery, *i.e.*, the surgery which abhors dogmatism, rut, and routine, and teaches its disciple to adapt his methods judiciously to each individual case, not shrinking from the most daring measures if the occasion demands them.

Radicalism is the offspring of over-specialization. The latter has worked greater injury to surgery than to any other branch of medical science. Who has not met a Themistocles in the ranks of surgical specialists, spending sleepless nights over the laurels of a Miltiades who happened to reach the high-water mark in the number of cases operated upon? The existence of such dangerous incentive "to swell the record" cannot be gainsaid: it means a mad race for numerical supremacy! Let me but point to those formidable windmills—formidable to the quixotic fancy of the gynecological fanatic—the irritable ovaries and thickened tubes. May the day soon dawn that shall free long-suffering womanhood from the daring grip of the professional unsexer! How far the absurdity may be carried was strikingly illustrated by the recent discovery that the waning charms, intellectual and spiritual, of our mothers, wives, and sisters may be restored by just a slight surgical coup-de main, *i.e.*, by a timely retraction of the præputium clitoridis; this would be ridiculous if it were not so utterly disgusting. I could go on indefinitely, but sapienti sat!

With the beginning of the era of rationalism in surgery we may justly hope for the rehabilitation to his former prestige of the "broad-gauge" surgeon, whose deft hand, keen eye, and perfect scientific equipment will enable him to embrace all the recesses of the human organism as a field of his activity. This will deal the death-blow to the puny mediocrity which, by confining its energies to a few square inches of the human frame, has fallen victim to hopeless cerebral strabismus.

It would be idle to put forth the claim that the physician should watch the development of things surgical as an uninterested observer, humbly submitting to the inevitable. In many an hour of anxiety and danger, after having exhausted his own resources, the physician appeals to the surgeon, and he ought to do so fearlessly, confident of his patient's receiving the full benefit of the most careful judgment and of the highest skill. As a physician shall I try, in what follows, to suggest one way of stemming the tide of radicalism.

Whenever conservatism raises its warning voice the opposing faction seeks shelter behind the rampart of—what they choose to call—statistics. It would be preposterous to decry the value of statistics in our age of census taking and scientific exactness. But to be valuable they must be complete or nearly so. Are the statistics on appendicitis able to withstand the search-light of scientific scrutiny? Are they anything more than a series of reports on successful or unsuccessful operations? How many hundreds, nay, thousands, of cases have passed through the hands of surgeons and physicians within the scope of a single lifetime, in which the wily appendix has flatly refused to live up to the blood-curdling expectations of his implacable foes! Why should our reputable journals refuse to lend a helping hand to the cause of truth and justice? preserving their neutrality, they shall act simply on the maxim of "Audiatur et altera pars." Reports on all non-operative cases should be invited: each case to be summed up epigrammatically in a dozen words, while stress should be laid on the length of the period of immunity and absence of all symptoms, subjective and objective. I am certain that the result would surpass the most glowing expectations of the friends of rational surgery. Unless some such step is taken, we should not be surprised to have a modern Moses appear in the midst of us, who would attempt to make prophylactic excision of the appendix a matter of law and custom.

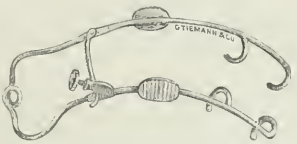
New Instruments.

A NEW EYE SPECULUM.

By William Holland Wilmer, M.D.,

Washington, D. C.

The speculum of which the accompanying figure is an illustration, has been used by the writer over a year with much satisfaction. The clearness of the cut renders a detailed description unnecessary.



It has been found that the instrument causes the minimum amount of pressure upon the eyeball, and owing to the perfect parallelism of the arms, it gives a large field for operating. It can also be used equally well for either eye, the fixation screw being so obliquely placed that it does not interfere with the knife. Moreover, it is very light and comfortable to the patient. It has proved especially useful in operations upon the upper and lower

muscles, on account of the construction of that portion of the speculum that supports the lids.

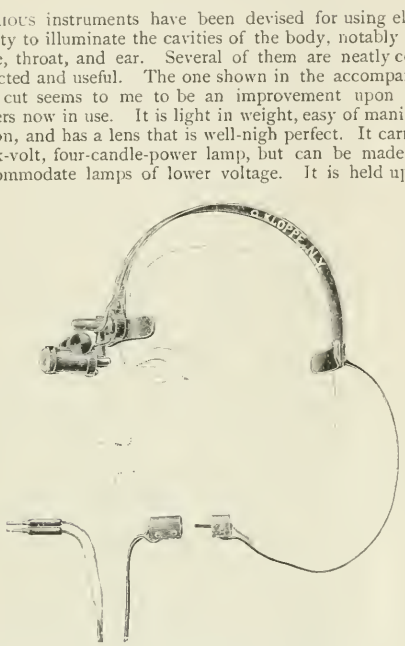
The instrument was made by George Tiemann & Co., New York.

A MODIFIED ELECTRICAL HEAD ILLUMINATOR.

By WENDELL C. PHILLIPS, M.D.,

NEW YORK.

Various instruments have been devised for using electricity to illuminate the cavities of the body, notably the nose, throat, and ear. Several of them are neatly constructed and useful. The one shown in the accompanying cut seems to me to be an improvement upon the others now in use. It is light in weight, easy of manipulation, and has a lens that is well-nigh perfect. It carries a six-volt, four-candle-power lamp, but can be made to accommodate lamps of lower voltage. It is held upon



the head by means of a steel band running from before backward, with sufficient spring to hold it in place. By means of the thumb-screw shown at the side of the lamp cylinder, the focus may be regulated easily and quickly. The experimental work in connection with this instrument has been done by Otto Kloppe, who is also the manufacturer. I have aided him by suggestions to develop it.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 1, 1893.

	Cases.	Deaths.
Typhus fever	2	2
Typhoid fever	17	6
Scarlet fever	63	4
Cerebro-spinal meningitis	5	6
Measles	161	12
Diphtheria	119	45

Cholera	0	0
Varciella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Pilocarpine in Threatened Mania.—Among the practical discoveries in therapeutics is the value of pilocarpine in threatened mania, and this is cause for congratulation, since the physiological action of the drug furnishes a scientific explanation of the manner by which the benefits are secured, namely, by stimulating the excretory functions. Willoughby, some time ago, reported the case of a man who was usually a sound sleeper, but for several weeks had been unable to obtain needed repose; during short dozes he would talk business, his appetite had failed, and for several days before his visit had scarcely slept or eaten. The patient was found in bed in a dark room with wet cloths on his head, singing, shouting, gesticulating, snapping his fingers, talking wildly, and seeing illusions, with a temperature of 104° F. After failure to procure sleep by the use of chloral and liquor opii sedative in substantial doses during a period of six hours, it was decided to use pilocarpine, one-sixth grain being injected into the arm at ten o'clock. Within five minutes profuse perspiration and salivation occurred, and the next morning the patient was perfectly calm and rational, the skin cool and moist, temperature less than half a degree above normal, head clear and appetite returning.—*The American Therapist.*

The Parish Doctor in Greece.—Dr. Kessner has an interesting article in the *Medical Magazine* pointing out that numerous tests and epigraphs exist to show that in every Greek city there was a public physician, whose duty it was to attend gratuitously both strangers and citizens, though practically only the poor claimed the benefit of his free ministrations. The inscriptions and bas reliefs from which this fact is ascertained are preserved in the British Museum. They consist of ten votive tablets, kept under glass in a small room near the mausoleum, with the sepulchral tablet of Jason and certain popular decrees throwing considerable light on the status of the medical profession in Greece.

The Health Department's Contribution to the Chicago World's Fair.—The exhibit of the Health Department of this city is now ready for shipment to the World's Fair. It consists of a handsomely bound volume containing samples of the different forms of certificates and circulars issued. The exhibit is ingeniously arranged, showing the work of the Department in every stage. There is an original complaint from a citizen about a tenement, and the blanks that follow show how the nuisance was investigated and finally abated. Accompanying the volume will be photographs of the various hospitals under the charge of the Department and the boats used in transferring the patients. A map of North Brother Island, showing the Riverside Hospital and other contagious disease pavilions, will also be shown.

McGill University, Montreal.—The chair of pathology and public hygiene in the medical school has recently been endowed by a gift of $100.000. The donor, who is also the chancellor of the university, is Sir Donald A. Smith.

ETIOLOGY OF THE VARIOUS DEFORMITIES OF HIP-JOINT DISEASE.[1]

BY A. M. PHELPS, M.D.,

PROFESSOR OF ORTHOPEDIC SURGERY IN THE UNIVERSITY OF NEW YORK AND THE NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL; PROFESSOR OF SURGERY IN THE UNIVERSITY OF VERMONT; SURGEON TO THE CITY HOSPITAL.

WE are all familiar with the deformities which occur in the first, second, and third stages of hip-joint disease. The typical deformities are: In the first, abduction, slight flexion, and outward rotation, with apparent lengthening (see Fig. 1); in the second, an exaggeration of the deformity which occurs in the first (see Fig. 2); while in the third stage the entire picture changes to that of flexion, adduction, inward rotation, and real shortening, with the heel resting upon the opposite instep (see Fig. 3). In a considerable per cent. of cases erratic deformities are observed; such as extreme flexion with outward rotation and shortening of the affected limb, the deformity of the second stage occurring in the third. Abduction and shortening, without flexion, is sometimes seen.

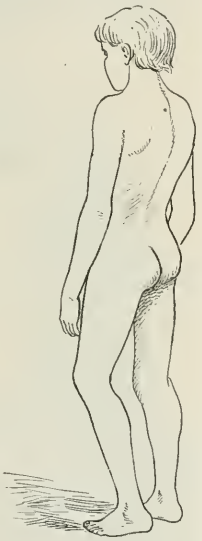

FIG. 1.

This division into stages is made merely for clinical convenience, and relates only to semeiology.

Barwell says that we may conclude that the appearances indicate certain processes of disease, but with morbid anatomy the division into stages has no direct connection. I have adopted this classification of the deformities in my observations and in writing.

A limb *with shortening, from destruction of bone*, I classify as belonging *to the third stage, without regarding the deformity present.* A limb with adduction, flexion, and inward rotation, I classify as disease in the third stage; even though there be no shortening, *I have observed in cases excised, that these deformities of the three stages, as already described, follow very closely, and quite accurately interpret, certain pathological changes taking place in, or about, the joint.*

The question under consideration is, what causes these various deformities?

1. Why does the limb assume, nearly always, the position of abduction, flexion, and outward rotation with fixation, in the first and second stages, and adduction, flexion, and inward rotation in the third stage? (See Figs. 1 and 2.)

2. Why, in a certain percentage of cases, do the deformities of the second stage occur in the third, *i.e.*, flexion, abduction, and outward rotation?

[1] Read before the American Orthopedic Association, September, 1892.

Barwell makes no attempt to explain these phenomena. I quote from his book:[1]

"While the muscles thus waste, the joint assumes a fixed position, natural in itself, abnormal only in its persistency toward the side of flexion. This is the case at the elbow, wrist, and ankle, while at the shoulder abduction pertains; at the knee an inward twist of the tibia is usually combined with considerable flexion; at the hip, very complicated positions, to be studied in a future chapter, are assumed. These postures assume in nearly every case of joint disease, almost with the certainty of an unchangeable law. There is, then, in all joint diseases, a tendency of the flexor muscles to contract, while the extensors, if not in absolute relaxation, do not, at all events, retract sufficiently to annul such action.

"It is true that the flexors are probably, in all limbs, stronger than the extensors, but in fact a mere examination will show that on the flexor side muscles are rigid, and on the opposite side flaccid. Our knowledge is as yet insufficient to account for the phenomenon."

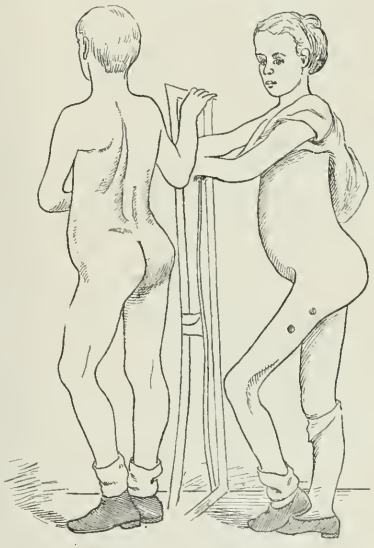

FIG. 2. FIG. 3.

We will consider these statements later. The experiments of the Germans demonstrated that the joint, when forcibly injected from within the pelvis, produced eversion, flexion, and abduction of the limb, and immobilization of the joint.

Sayre concludes from these experiments, that effusions are present in the joints diseased, that this intra-capsular hydraulic pressure is the cause of the deformity in the first and second stages of hip disease.

He says (p. 248): "The peculiar position of the limb gives to the second stage of the disease the name 'apparent lengthening,' but I prefer to designate it as the stage of effusion."

And he accounts for the deformity of the third stage, viz., flexion, adduction, and inward rotation, by the

[1] Barwell, p. 106. Wood's Library, 1881.

rupture of the capsule and the escape of the fluid, thus relieving intra-articular pressure. This, he claims, allows the leg to swing to the deformity of the third stage. He says (p. 259):

"And rupture of the capsule takes place and the imprisoned fluid escapes into the surrounding tissues. When this has occurred the disease is in the third stage.

"The limb is now adducted, inverted, and flexed.

"The change in position is due to the fact that the fluid in the joint cavity has been evacuated.

"The distention of the capsule, which was the mechanical cause of the flexion and adduction of the limb, having been relieved, nothing now obstructs the free action of the adductors, and the limb is therefore adducted and inverted."

So far as I know, this hypothesis of the Germans, approved and indorsed by Dr. Sayre, is the only explanation we now have of the etiology of the various deformities of hip-joint disease. Barwell offers none; but makes, among others, a broad statement that, "It is true that flexors are probably, in all limbs, stronger than extensors."

A moment of thought will convince us that this last statement is certainly an error.

In the knee-joint the quadriceps is much stronger than the flexors. This we have demonstrated in the course of our experimental work, and it will be published shortly. The same is also true of the hip-joint. The fluid hypothesis is certainly erroneous, for the following reasons:

1. A very large per cent. of cases of morbus coxarius are unattended by fluid effusions. *Still, the same picture of deformity is seen as in those cases attended by large effusions.*

2. I have observed in our clinics and have operated upon cases of *extra-capsular disease, in which the joint was not diseased, but the same picture of deformity presented itself.*

Barwell says (p. 292) "While inflammation, or even suppuration about the epiphysis of the femur arises, certain pains, forms of lameness, etc., are produced; while as yet there is no effusion or suppuration within the joint cavity; no morbid changes of the parts which form its walls. We have, namely, so-called symptoms of morbus coxarius, while as yet in the hip (joint) there is no disease."

3. Cases of suppurating joints, with large effusions, often take the erratic deformities of the third stage—*i.e.*, abduction, flexion, and outward rotation—even after the joint contents have discharged.

4. There can be no reason why, after the evacuation of the joint, the limb should not return to the deformity of the second stage instead of the third; because the three great glutei and outward rotators are stronger than the adductor group, unless the limb is flexed beyond twenty degrees. These are the chief, and I believe, valid reasons why the explanation of these deformities by the fluid hypothesis is incorrect.

I have become fully convinced that as yet a correct explanation has not been offered for these deformities.

After concluding several dissections of the hip-joint, I desire to place before you for your consideration and criticism the theories and hypotheses upon which we worked, and the conclusions at which we arrived.

It became necessary, before any experimental work was performed, to carefully compile clinical data in a large number of cases. Assisted by Drs. Plympton and Greenway, these observations were made at our clinics at the University Medical College, and also at the Outdoor Department and the Orthopedic Ward of the New York Post-Graduate School and Hospital, two places which afforded us ample opportunities for observation. The conclusions reached were:

1. That abduction nearly always preceded flexion, or was attended by it, in the first stage.

2. Abduction and outward rotation, are always present in the second stage. Flexion was nearly always present, but was absent in a few cases.

3. When the limb flexed beyond forty degrees, and frequently at a much lesser degree (twenty degrees), it quite rapidly passed to the deformity of adduction, inward rotation, and flexion, *whether the capsule contained fluid or not.* (The degrees alluded to are from a horizontal plane.)

Fig. 4.

4. A few cases exaggerated the deformity of the second stage for the third. In other cases there was outward rotation, abduction, shortening, with but slight flexion in the third stage. (See Fig. 4.)

In another case, observed by Dr. Plymptom, adduction and inward rotation, without flexion, occurred with three-fourths of an inch shortening. (See Fig. 5.)

Fig. 5.

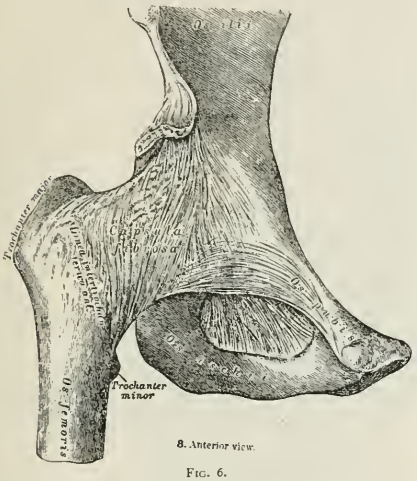
5. That there was always spasm and contraction of muscles about the joint, and *in nearly every case all the various groups were in a state of spasmodic contraction.* That shortening annulled or modified the action of the flexor and abductor group.

These observations, together with dissections which Dr. Greenway and I made, presented numerous problems which will be considered later. At the University dissecting-room, we made a series of dissections, from which, I think, a fair explanation can be given of every deformity which may occur in any case of hip disease.

The hip-joint is surrounded on its outer aspect by a mass of muscles running diagonally from the pelvis to the great trochanter from all directions. When the limb is in a straight position, the combined action of these muscles produces abduction of the limb. The capsule is wound around the neck of the bone. The tension of this capsule, together with that of the Y-ligament, holds the head of the bone firmly in the socket and produces great

pressure upon the joint when the limb is in the straight position. (See Fig. 6. Straight position.)

The great adductor group of muscles pass diagonally downward from the pelvis and are inserted into the shaft



8. Anterior view.

Fig. 6.

at the femur posteriorly along the linea aspera. (See Fig. 7.)

The flexor group arises from within the pelvis, passes downward over the pubes, taking a reinforcement which arises from the anterior surface of the capsule of the joint, and is inserted into the lesser trochanter. This group acts over the pubes as a cord over a pulley, *and its power increases as the leg flexes.* This flexor group is antagonized by the inferior portion of the glutæus maximus.

Fig. 7.

The external rotators are antagonized by the tensor vaginæ femoris and a portion of the glutæus minimus and medius. Thus we have the several groups in their respective order when the limb is in the straight position, viz.:

Glutei group, abductors, antagonizing adductor group.

Flexor group, antagonizing extensor group.

External rotator group, antagonizing internal rotator group.

To determine the relative strength of each group the muscles were weighed separately, and the triangle in which they operated measured, as also was the length of lever upon which they operated. The glutæus maximus muscle, which weighed two and one-half pounds, acting in a triangle formed by a line drawn from its insertion near the great trochanter to the centre of the head of the bone, three inches; from the head of the bone to the origin of the muscle, six inches; from its origin to its insertion, six inches, was assumed to be capable of lifting fifty pounds one inch. This was taken as the unit of strength. Other triangular muscles of different weights, operating in dissimilar triangles, could be accurately estimated as to their comparative strength. The rule which I followed was that laid down by Haughton (see "Haughton's Principles of Animal Mechanics," p. 183), from which I quote:

"The work done by the same (a triangular) muscle will be proportional to double the perpendicular, let fall upon the side of a triangle from the foot of the bisector of the vertical angle." The quality of the muscular fibres of each group very closely correspond. In each group are found fine or coarse muscular fibre in about the same proportion. The rule applied to ascertain the relative strength of the great adductor and abductor group gives to the adductor group a decided advantage, because they stand parallel with the plane of the triangle, whereas the glutei muscles do not, but were so measured and estimated. In spite of this advantage given in the estimates the abductor group acting on the shorter lever was found to be much stronger than the adductors, the proportion *being one hundred and thirty-one pounds for the abductors to one hundred and sixteen pounds for the adductors in the subject examined.* Then, when all the muscles are affected by spasm equally and the limbs parallel, the abductors would produce abduction because of their superior strength.

From our clinical observations *I at once concluded* that the reason why the limb went over to the deformity of the third stage of hip-joint disease *was because the action of these muscles were all changed by the flexion of the limb, or from pathological destruction of the joint changing or annulling the action of the muscles by destroying the leverage, or localized irritation of nerve-plates in the area of disease, producing spasm of groups of muscles receiving nerve-supply from the same common trunk.*

The question of nerve-distribution within the joint quite surely plays an important part in determining deformities occurring in circumscribed foci of disease. But after the entire joint becomes involved, this element must be left out of the question only so far as general spasm is produced in all muscles about the joint. I quote from a letter of Dr. Towle, Professor of Anatomy in the University of Virginia, which seems to demonstrate that the nerve-supply comes from different trunks:

"As to nervous supply of hip, what I have seen is as follows: The obturator immediately on emerging through the obturator foramen gives a branch which pierces the capsule; the sacral plexus, or upper part of great sciatic, gives off two small branches which enter the back of the capsule; the nerve to obturator internus, from sacral plexus, leaving through great sacro-sciatic foramen, gives a branch to back of capsule. What particular structure of joint is supplied by each I cannot say, as I have only traced it to capsular ligament."

When the limb becomes flexed, the abductors begin immediately to lose their power as abductors, and in proportion to flexion become inward rotators.

Figs. 8 and 9, taken from the dissections, represent the glutæus medius, with the limb in a straight position, and then flexed to thirty-five degrees. *In Fig. 8 the muscle acts as an abductor, while in Fig. 9 its action is changed to that of an internal rotator when the limb is flexed to thirty-five degrees.*

Figs. 10 and 11 are from photographs of our dissections of the glutæus minimus. In Fig. 10, the limb straight, the muscle acts as an abductor, and feebly as an internal rotator; whereas in Fig. 11, the limb being flexed only fifteen degrees, it becomes a powerful internal rotator and increases in power as the limb flexes, as does also the tensor vaginæ femoris (see Fig. 11): the outward rotators become abductors when the limb is flexed to an angle of about forty degrees, with the exception of the quadratus femoris and obturator externus. The change of action in the other muscles is quite as marked as in these which have been illustrated and presented as examples. (See

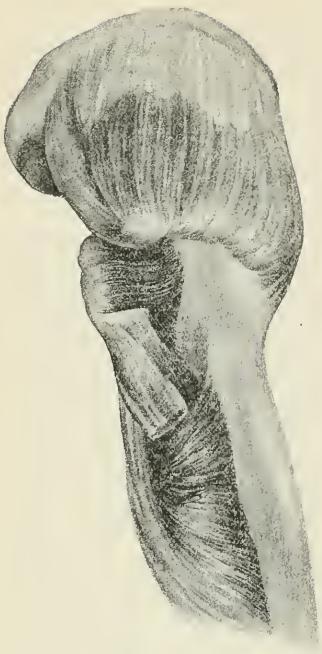


Fig. 8.

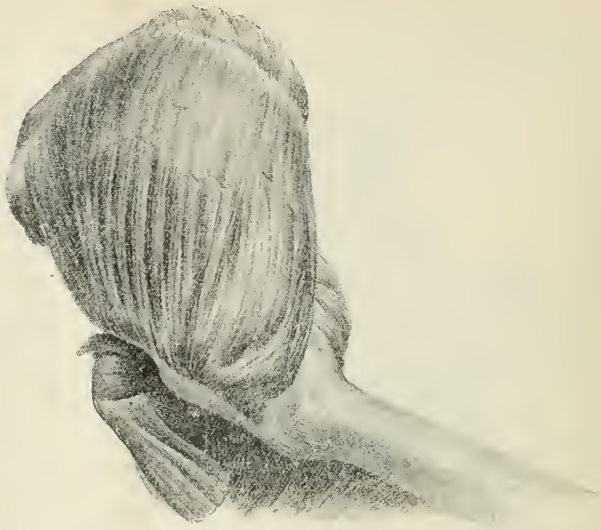

Fig. 9.

Fig. 11.) This brings us to a consideration of the problem before us.

Question 1. Why in the first stage is the limb slightly abducted, outwardly rotated, and flexed with apparent lengthening?

Answer. A voluntary effort on the part of the patient to relieve tension of the capsule and Y-ligament. (See Fig. 6.)

Question 2. Why does this deformity increase, constituting the second stage of the disease?

Answer. Spasm of the muscles about the hip-joint is present. The great glutei, outward rotators, tensor vaginæ femoris, and flexors acting together have the advantage of leverage and strength (being irritated and affected by spasm, and aided by a voluntary effort, or non-resisting effort of the patient, the same as in the first stage) the limb still exaggerates the deformity of the first stage.

Question 3. As a rule, with an occasional exception, why do limbs assume the deformity of the third stage only after flexion to twenty-five degrees has taken place?

Answer. Because after the limb passes to twenty-five degrees of flexion, the abductors to a very great extent *become internal rotators* (see Figs. 8, 9, 10, 11); the *external rotators almost totally lose their power as external rotators* (see Fig. 11), *and become abductors*, with the exception of the quadratus femoris and obturator externus, and the tensor vaginæ femoris becomes a powerful inward rotator. Resistance or antagonism to the powerful abductors and flexors of the thigh being modified or annulled by flexion, the limb must pass to the deformity of the third stage, namely, adduction, flexion, and inward rotation.

Question 4. Why did some cases in the third stage of the disease continue the deformity of the second?

Answer. These may be, and usually are, cases char-

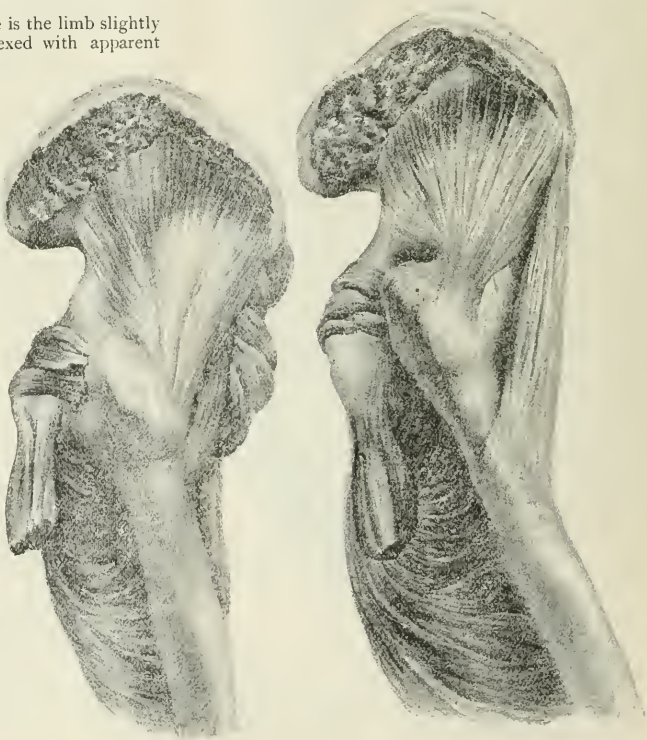

Fig. 10. Fig. 11.

acterized by great abduction and outward rotation from the commencement of the disease, or soon after. Many of these erratic deformities occur in bed cases from positions of ease assumed while lying. In others the head of the bone is thrust forward against the anterior and upper border of the acetabulum, cutting it away, producing a partial dislocation forward. This extreme abduction puts the adductors on the stretch and partially paralyzes them by tension. The abductors and outward rotators become permanently contractured, adhesions form, and the limb is held in this extreme position of deformity of the second stage in the third.

I have excised two cases of this deformity, and in both cases the head of the bone had perforated the acetabulum anteriorly and superiorly, and the bone was held firmly against the pelvis by bands of adhesions.

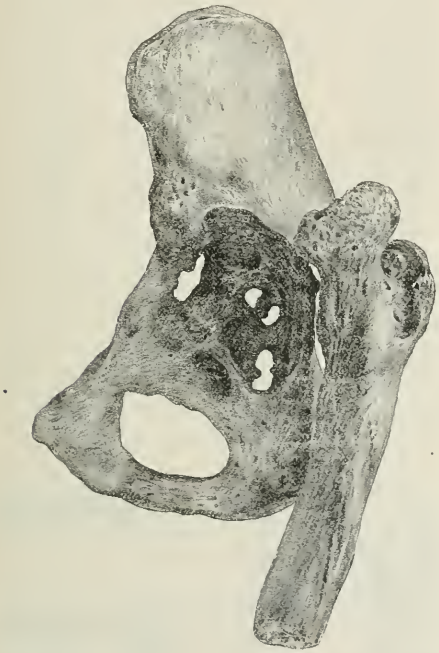

FIG. 12.

Fig. 12 is taken from a photograph of a case where the head of the bone had cut away the acetabulum anteriorly and superiorly, and was about to escape through the openings forming in the acetabulum into the pelvic cavity.

Dislocations may take place anteriorly or posteriorly: posteriorly often from large effusions or other pathological cause; but anteriorly from destruction of the anterior border of the acetabulum, due to the action of the external rotators and glutei muscles and destruction of bone from disease. *The shortening of the neck of the femur destroys the action of the flexors and the abductors by changing the leverage.*

Question 5. Why did one of the cases have adduction, outward rotation, and shortening without flexion? (See Fig. 4.)

Answer. Because of the destruction of the head and neck of the femur, or the passing of the head through the acetabulum *anteriorly*. This destroyed the leverage of the glutei and flexors, which gave the adductors full power to adduct while the external rotators still acted. The same cause explains the deformity in Fig. 5, only the head took a *backward* course owing to *destruction of bone in that part of the acetabulum.*

Nerve-distribution within the joint undoubtedly plays an important part in producing special action of groups of muscles, depending upon the location of the lesion. As, for example, in the knee-joint flexion is never seen in disease of the patella alone. This is due to the fact that this portion of the joint is supplied from the anterior crural nerve, which trunk supplies the extensors of the

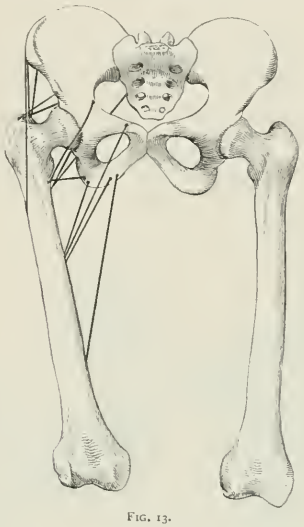

FIG. 13.

limb, and not the flexors. Whereas flexion occurs in disease of the condyles, the nerve-supply of which is derived from the great sciatic, which nerve-trunk supplies the flexors and not the extensors of the limb.

To further illustrate the action of the muscles about the hip-joint, the limb being straight and then flexed, I

FIG 14.

present this manikin, with rubber straps so placed as to represent the action of the various groups of muscles. Fig. 13 should represent the limbs parallel, but the artist failed to place them so. Abduct the limb, as seen in Fig. 14, and the pelvis tilts and the right limb appears too long. This relieves the pressure within the joint by unwinding the capsule (see Fig. 6), and puts the ad-

ductors on the stretch, enfeebling their action until flexion commences, or the head and neck are destroyed by disease. The abductor group being stronger, holds the limb in this position. (See Fig. 15, side view, limbs parallel.) Then as flexion commences the action of every muscle is changed or modified (see Fig. 16), and the limb must assume the position of the third stage of hip-joint disease, viz., flexion, adduction, inward rotation.

Conclusions.—Normal or typical deformities are produced by change of leverage and actions of muscles due to—1. A voluntary effort. 2. Involuntary spasm or contraction of muscles. 3. Nervous irritation of groups of muscles due to location of lesion in or about the joint.

The erratic deformities are produced by change of leverage, due—1. To pathological causes, *e.g.*, destruction of bone, head, neck, or acetabulum. 2. Nervous irritation of groups of muscles, due to location of lesion in and about the joint.

FIG. 15.

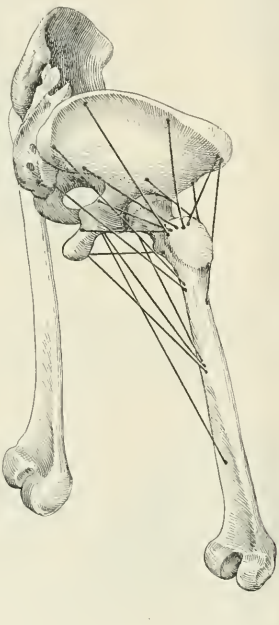

FIG. 16.

The pathological causes of erratic deformities are—1. Shortening of the head and neck of the femur. 2. Perforation of the acetabulum. 3. Shortening of the limb from either of the last-named causes. 4. Burrowing of pus through groups of muscles, either irritating them to contraction or destroying them. 5. Dislocations from destruction of bone. 6. Dislocations from large effusions. 7. Cicatricial contractions binding down and restricting the limit of motion of the femur.

The explanations of the cause of the deformities existing in hip-joint disease is applicable to every joint in the body, and very soon I will publish the result of experiments on all the other joints.

I have for the sake of brevity omitted the mathematical work, and also the results of the study of the action of flexor and extensor groups, for to my mind they play altogether a secondary part in the drama.

The reader at once asks the question, "Why all this work? what good can come of it?" I will briefly answer: In the treatment of hip-joint disease fixation to prevent motion, and extension to overcome intra-articular pressure, is the law of treatment.

We have observed that these great and powerful groups of muscles act upon the thigh with so much force as to produce great deformities. That the patient voluntarily assumes certain positions to relieve the tension of the capsular ligament *whether there is effusion or not. That these groups of muscles do not act on an axis with the*

FIG. 17.—The Cheap Dispensary Splint.

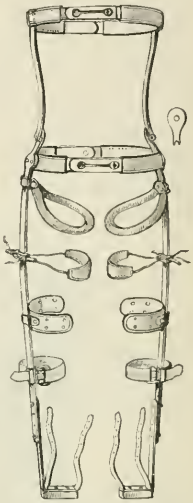

FIG. 18.—The Double Dispensary Splint.

shaft, but nearly on a line parallel with the axis of the neck of the femur. From these facts we must decide that to relieve intra-articular pressure by overcoming the contraction of the muscles *traction should be made in the line of the axis of the neck and not of the shaft.*

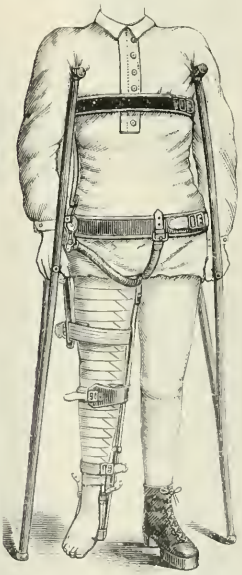

FIG. 19.—The Patient Splint, Adjustive High Shoe, and Crutch.

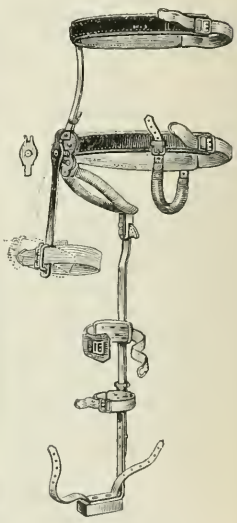

FIG. 20.—Inside Bar and Lateral Traction-lever.

Patients with deformity should be put to bed with two lines of extension, one in a line with the axis of the shaft and deformity, and the other at right angles to the shaft. Then when the deformity is overcome I place them

on a lateral traction fixation-splint, which I devised, with a high shoe on the well limb, and a pair of crutches, and allow them to take plenty of out-door exercise. A glance at the cuts will convey the idea.

The thoracic portion is necessary to fix the joint. *It is argued that the patient cannot sit down. This is incorrect.* The patient sits on the *side of a higher chair and the leg and splint fall to the side.* Sayre says the patient's leg must stick out and be in the way.

So must it do when his knee-splint is adjusted. He also says anchylosis must result from this fixation, that motion is necessary to prevent this accident. *I have not observed bony anchylosis nor angular deformity in over two hundred cases, many of whom have been fixed from one to four years without motion.*

Sayre's knee-splint fixes the knee by extending from below to above the knee without a joint. If fixation is good for a diseased knee, why is it not good for a diseased hip? Is there any difference in the treatment of the same diseases, whether in the hip or in the knee? Should we have a plan of fixation for the knee and motion for the hip?

Shaffer's statistics *show anchylosis in about sixty per cent. of his cases reported. He uses the long traction splint, essentially the same splint used by Sayre, Taylor, and others—one that permits of free motion at the hip-joint. The patient is allowed to walk upon the splint, and nearly every case recovers with angular deformity. This is wholly unnecessary. No case need recover with bony anchylosis or angular deformity.*

I do not pretend to have solved all the problems of the causes of the deformities occurring in morbus coxarius; but I offer this paper as a preliminary one to further study of this most complicated joint in a condition of disease.

FIRST AID TO THE INJURED, FROM THE ARMY STAND-POINT.[1]

By MAJOR CHARLES SMART, U.S.A.

Provision for first aid to the injured has been the subject of earnest study by medical officers of our army for several years back. The War of the Rebellion gave the Army Medical Department a large experience which has not been altogether lost by lapse of years; for although most of those who were personally engaged on the great battle-fields have dropped from the ranks of active workers, many of them have placed their views on record or impressed them on younger officers who have served with them as subordinates.

In the way of efficient arrangements for the administration of first aid in our military service there have been two obstacles which greatly delayed our progress. Ordinarily the paramount duty of a military bureau in times of peace is to keep itself in training for the emergencies of future war; but the quarter of a century of peace and prosperity enjoyed by our country since the close of the Civil War has been so beset with Indian hostilities that the Medical Department has had little opportunity of keeping itself in proper training. This seeming paradox is due to the fact that the conditions of field service against the Indian tribes differ so radically from those of civilized warfare. Under the latter there is always some place of relative safety toward the rear or base of supplies where the wounded may be gathered and become the object of systematized care, no matter what may be the issue of the contest. Under the former, on the contrary, there is no such place. There is no rear for the men of a cavalry troop assailed by Indians many days' march from the nearest military post; there is no protection for the wounded save what is afforded by the nature of the ground held by their comrades, and every available man must fight until the savage enemy becomes disheartened and withdraws, or is driven off by fresh arrivals on the scene of action. Systematic methods for aid to the wounded have little opportunity for development under such conditions. Witness the fate of General Custer and the men of the Seventh Cavalry at the Little Big Horn River. Assistant-Surgeon Lord and his hospital men merely accompanied the soldiers to their death.

The difficulty of providing first aid to such expeditionary columns, operating in a country impassable for wheeled vehicles, by a system which, on enlargement, would meet the necessities of civilized warfare, was one of the obstacles which delayed the progress of the Medical Department of the army in this direction until the past few years. The other obstacle was the failure of that vague power known in military parlance as superior authority to provide suitable men for hospital purposes. Medical officers generally got what they wanted during our great war on account of the extent and importance of their field of practice. Thus, when a medical director called for certain men for hospital duty, he usually obtained the good men he asked for. After the war the whole military establishment fell back almost to its ante-bellum status, and when the medical officer of a military post asked the commanding officer of that post—probably the captain of the only company stationed there—for certain men for hospital work, it by no means followed that he got the men he asked for. The commanding officer disliked to lose good soldiers from the ranks, but readily spared any man who was broken down, valueless from innate stupidity, or worse than worthless from dissipation. The men whom he could get, not the men whom he wanted, were those that the medical officer had to prepare for the duties of giving first aid to the injured; and afterward, when, by dint of care and assiduous personal attention to their physical and moral well-being he had repaired the broken constitution, awakened the intelligence, uprooted the evil habits, and endowed these men with possibilities of future worth, they were probably transferred to the ranks and the hospital provided with substitutes as worthless as those that had originally been sent. After laboring in vain to build a hospital system with such bricks, the most enthusiastic medical officer generally subsided into a state of resignation, or gave vent to his suppressed energies by formulating for the benefit of the Surgeon-General what seemed an Utopian dream of a hospital corps, every member of which was sober, trustworthy, and intelligent, and fully conversant with every duty that the exigencies of the service might call upon him to perform. Not, indeed, that the Surgeon-General was ignorant of all this, but that superior authority was slow to move the wheels of progress out of the old-time ruts.

However, in 1887, Congress was led to appreciate and remove one of these great difficulties in the way of first aid to the injured soldier by authorizing the organization of the Hospital Corps; its members to be selected, educated, drilled, and disciplined by the medical officers themselves; whereupon these officers began earnestly to build up the organization and to so systematize its work that the same principles would regulate its action in times of peace as in times of stupendous war. This work is now well in progress, but with its methods the present paper has no concern, as it is limited to the executive details of first aid. To understand these details, however, a slight reference to certain of the administrative methods is needful.

General aptitude or intelligence, with some primary or elementary education, is a *sine qua non* to enlistment in the Hospital Corps. On this selected soil the medical officer has to raise all the technical knowledge of disease and injury that is necessary to enable the individual to do good and not harm when his responsibilities come upon him and he is face to face with some appalling accident with no intelligence but his own to guide the hand that is to succor. All men, citizens or soldiers, who are to render first aid must have more or less of this knowledge, because the clearer their perceptions of what

[1] Read June 17, 1893, at the meeting of the International Congress of Charities, Correction, and Philanthropy, Chicago, Ill.

is to be done the greater will be their self-possession and ability to act. People generally lose their heads in the presence of accident and suffering. The man who knows something of what has to be done preserves his presence of mind. If he has been familiarized by drill in the management of emergencies with the idea of his own responsibility, he retains his presence of mind and ability to do good although knowing little of the conditions or special treatment of the particular case. The advantages of drill in first aid are obvious; but its importance to the Hospital Corps soldier is vastly greater than to the citizen Samaritan. Drill and its correlated discipline have to support him in his duties to the injured under the appalling knowledge that he is himself liable to be struck down at any moment. He must retain his presence of mind not only when confronted with death and injury to others, but when every rifle-shot and bullet hum suggest the imminence of personal danger. Great courage or thorough discipline, or an adequate combination of the two, is required under such conditions for the performance of duties calling for the exercise of knowledge, tact, delicacy, and a humane consideration for the sufferings of others.

Behold, then, the men on whom the injured of the army have to rely, men to whom no Christian would deny the honor of wearing the cross of Christ as the badge of their military service. The points next in order are, what do they do, and how do they do it?

First aid to the injured in war has not the same extent of significance to the soldier as to the citizen. To the latter it means all that is done on behalf of the wounded until they are *en route* from the privations, exposures, and dangers of the battle-field to the shelter, care, and comforts of permanent hospitals. In fact it comprehends the whole battle-field service of the Army Medical Department—the gathering of the fallen by the litter-bearers, their transportation by ambulance wagons to the field hospitals, and their preparation there for transmission from the lines of the army for their homeward journey by way of the post or station which is the base of military operations. To the soldier, however, first aid is that which finds him where he fell on the skirmish line or line of battle, which puts a canteen to his lips to revive him, stops the flowing blood, straightens the fractured limb, giving him cheering words meanwhile, and carries him to the friendly side of the house a little way off, or behind the breastworks, or over the brow of the hill, where he will be safe from stray bullets, and have the doctor help to make him comfortable before transferring him to an ambulance for transportation to the field hospital. When first aid has done these things it has done all that the soldier expects, all that he wants, for when he reaches the canvas tents of the hospital where the skilled operative surgeons of each brigade are at work, and where all the resources of the medical department are drawn upon for the comfort of the wounded, he takes his bowl of beef-tea and disposes of himself to rest, satisfied that whatever may hereafter be done on his behalf is not in the nature of first aid but in that of regular hospital treatment for his wounds. The soldier's view is the correct one and is the analogue of the citizen's view of first aid in all cases excepting only that of the battle-field.

When the command with which a medical officer and a detachment of the hospital corps are on duty is in line of battle and in momentary expectation of the outburst of the storm of war, the nearest shelter from musketry fire is sought whereat to establish the collecting- or dressing-station for the wounded. When the same command is in camp with no danger of immediate hostilities the medical officer and his men are in camp also and ready at all times to render aid in accidents and injuries. Again, when in times of peace the troops form the garrison of a military post, the medical officer and his men are still to be found in the immediate vicinity of the quarters of the soldiers, the medical establishment being then known as the post hospital. This hospital, however, is from our present point of view merely the collecting-station of the battle-field, so altered by the various additions and comforts that have crystallized around it during the unruffled quietude of the times as to be scarcely recognized at first glance. Here is to be found all that contributes to first aid to the injured and with it much more that is of high value; but with this surplus we are at present not concerned. Does an accident happen at this military post, immediately a litter squad, equipped as for the field of battle, is on the ground to care for the injured man and bring him to the post hospital. Does the command participate in some military parade, the medical officer and his detachment, with litters, ambulances, and field equipment, are there also, not for show, but for first aid. Where the command goes there goes the hospital corps; and when the former cuts loose entirely from the post, as frequently happens in our Western service, the latter does so likewise and is as fully prepared to meet the emergencies of field service as it was to meet the accidents of garrison life. It carries with it its litters and other requisites of first aid, and its ambulances as the basis of a hospital system. When several such commands meet and are united into one force under the senior commander the several hospital corps fragments coalesce into one whole under the senior medical officer. When hundreds of such commands are gathered together in time of war the medical organization progresses step by step with the organization of the commands into an army, and when this is completed no part of the column, when on march, nor of the line when formed for defence or attack, is left without its medical officer and his orderly and his assignment of litter-bearers for first aid to the injured.. If one part of the line suffers more severely in battle than another, the supervising authority of the medical corps on the field sees to it that a corresponding increase of force is placed on their duty there; but the working elements of this force continue to be the medical officer, his orderly, and his litter-bearers.

A provision of this kind is of immense value to an army irrespective of all considerations of first aid to the injured. The assurance that he will be taken care of should he fall exerts a steadying influence on the soldier which improves the morale of the fighting line. In the progress of battle, however, the very integrity of this line is often dependent on the vigorous and efficient action of the hospital corps. Ranks are speedily depleted if men drop out to assist a wounded comrade to the rear, and the thinning of the ranks has a serious influence on the spirit of those who remain. So thorough a depressant is this depletion that military men have made calculations as to the percentage of loss which an organization can sustain without losing its identity and disappearing from its place in the line. An efficient hospital corps which comes to the front for the wounded deprives the men of all excuse for leaving their position. It is true our present army regulations provide for the education in first aid of four men from each company. These men are called company bearers, and their duty outside of the regular duties of a soldier is to assist the wounded from the field until relieved by the members of the hospital corps, when they return to their places in the firing line. The company-bearer system is now recognized as a mistake. It is a survival from the time when there was no hospital corps, and when the wounded had to find their way to the rear with such assistance as their friends could give them. It was embodied in our hospital corps law as a source of recruits for the corps which was to be organized and sustained by transfers from the line of the army, and those who took kindly to the duties of company bearers were naturally the best men for transfer. Now the hospital corps can enlist its men from any source, and the only method of showing the need of company bearers is to show that the litter squads of the hospital corps are incapable of performing their duty.

The litter consists of a canvas bed 6 feet long and 22 inches wide, made fast to two poles 7½ feet long, and

stretched by two jointed braces. The ends of the poles form the handles, 9 inches long, by which the litter is carried. The fixed iron legs are loop-shaped, 4 inches high and 1¾ inch wide. A sling is used with it for long-distance carriage. It is carried closed or strapped, and is opened only for purposes of drill or inspection and for actual service in the transportation of the sick and wounded.

The bearers work in squads of four men, known individually as No. 1, 2, 3, and 4. The litter is carried by 2 and 3; 1 and 4 are on either side, and the former is chief of squad. All carry water and dressing-packets, but No. 4 has, in addition, a pouch containing field surgical necessaries. These men march into the exposure of the field for their wounded. When a patient is discovered 1 and 4 may run ahead to determine his condition. In the various accidents of civil life or of military garrison life this oftentimes requires much knowledge, with time and patient inquiry and investigation. On the battle-field the questions are simpler, being mainly reduced to a determination of the conditions that bear upon transportation on a litter for a short distance and a corresponding time. Do shock, hemorrhage, or fractured bones have to be cared for, a draught of water, with or without a stimulant, a field tourniquet and intelligent care in handling one or more are at hand as required; and perhaps by the time Nos. 2 and 3 have arrived with the litter, No. 1 is ready to command: "At patient;" right (or left as he may consider best), when the members of his squad, each at his post, kneel on one knee by the wounded man. "Prepare to lift; lift," he commands, and the patient is immediately removed from the ground and resting on the knees of three of the bearers, while the other places the litter along their front. "Lower patient," and the injured man is laid gently on the litter and adjusted thereon according to the requirements of his condition or injury. Then, at the command, "Prepare to lift; lift; forward, march," they are off with their burden, moving rapidly but without haste and without jolting or other unevenness of movement. All this is accomplished almost automatically. The orders are given and obeyed, and the wounded man is on his way from the exposure of the field in less time than would have been lost by intelligent but undrilled men in determining how best to raise their patient from the ground. The best methods have been studied for them and practised by them, so that when moments are precious and delays dangerous there is no time lost by ignorance, awkwardness, or indecision. Even in the adjustment on the litter, practice makes it a matter of course to support and comfortably raise the head by an overcoat, blanket, blanket-bag, knapsack, or other suitable article picked up from the field; to raise the patient further if there is difficulty of breathing, but to keep him low if, from shock or loss of blood, there is danger of fainting; to place him on his back or injured side if the abdomen is wounded, with a pillow under his knees to keep them bent; to place an injured arm over the body, and to bind a fractured leg to its fellow for the sake of its support.

The litter squad may not do any more for the wounded man than has been stated, but its members can do more if there is time, opportunity, or necessity. They do no more if other wounded men are awaiting removal, if there is notable danger from the fire of the enemy, or if the collecting-station be close at hand. What they are able to do may be understood from a glance at the contents of the hospital corps pouch which No. 4 carries slung from his right shoulder to his left hip. It contains a candle and matches, lest there should be need of artificial light, the tin case acting as a candlestick when required. Then there are two field tourniquets and a vial of aromatic spirits of ammonia for dealing with internal hemorrhage and shock, as already instanced. Held together in a small leather book are a pair of scissors, dressing-forceps, jack-knife, pins, needles, and thread. Packed loosely in the pouch are three five-yard rollers of two and one-half inch antiseptic bandage, a strong metal box containing fifteen yards of adhesive plaster one inch wide, another box containing one-half ounce of two per cent. carbolated vaseline, a hard-rubber iodoform sprinkler, two sponges in a water-proof bag, a first-aid package, a two-ounce packet of sublimated lint and another of boric wool, and lastly, two wire splints with six strong tapes and buckles. The first-aid package, an extra one of which is carried by each of the members of the squad, requires to be opened to appreciate its possibilities. Its wrapper is strong rubber-cloth, nine inches square, and its contents two yards each of sublimated gauze and cambric, four inches wide, a triangular bandage, and two safety-pins. The bandage measures fifty inches along its base, and half of that measurement to its apex; it is stamped with figures showing the method of its application to the various parts of the body, either as a support or as merely retentive of dressings.

The intentions of first aid to a wound are to arrest hemorrhage, remove foreign bodies, prevent bacterial invasion, and protect from injury during transportation. The wound has to be laid bare, to effect which the scissors, if need be, are used along the seams of the clothing. Dried and clotted blood, fragments of cloth, or other foreign bodies have to be removed, capillary, venous, or slight arterial hemorrhage to be checked, and the whole thoroughly cleaned, dried with antiseptic gauze, dusted with iodoform, and protected with a compress of gauze and a suitable bandage. Adhesive strips are used to secure apposition of the sides of incised or gaping wounds. If there is fracture of the bones of the arm or forearm, the splints have to be applied with the triangular bandage as a sling. The splints may also be used in fractures of the leg and thigh; in the latter as aids to a long splint obtained by improvisation. The members of the litter squad can apply rifles, sword-blades, and scabbards, telegraph-wire, straw, strong grass or rushes, as temporary supports in fractures; they can utilize all kinds of cardboard and other stiff materials, and with their heavy sheath-knives they can hew the splint that is required out of that which at first sight might look like most unpromising timber.

At the collecting- or dressing-station are gathered many men who were able to reach this place of aid and comparative safety without assistance. The non-commissioned officers and men of the hospital corps attend to these cases while the medical officer deals with those of greater severity. In many instances the first aid given by the latter differs in no way from that which would have been given by his litter squad, but in every case he is prepared by the higher grade of his knowledge to render more valuable services if such should be required. His orderly, who always accompanies him, carries his pouch of field necessaries, such as are found in that of the litter squad, but containing in addition an Esmarch's tourniquet, a four-ounce bottle of chloroform, a hypodermic syringe with tablets of morphine, and a book of button-holed tags, by which he may convey information to the hospital surgeons concerning a particular case, fastening the tag over a button to the patient's breast. This pouch is furnished also with a small leather case of six screw-top vials, containing tablet doses of acetanilid, sulphate of quinine, compound cathartic pill, of brown mixture and diarrhœal remedy, and lastly, tablets of corrosive sublimate and sal ammoniac, each equal to one pint of a .001 sublimate solution. Slung on his own shoulder the medical officer carries his field-case, which, if examined, will show to what extent he is prepared to aid the injured. In it there are a bistoury, scalpel, and amputating knife, the blade of the last four and three-quarters inches long, a saw, scissors, artery, bone, bullet and dressing-forceps, Nélaton's probe, director, aneurism needle, tenaculum and serrefines, needles, ligature silk and wire, and a catheter.

The wounded brought in by the litter squads are examined by the medical officer without disturbing the dressings except in those cases in which there are obvious reasons for so doing. If they have been carried off

hurriedly, undressed, they receive immediate attention at the hands of the non-commissioned officers and men of the station, under the supervision of the medical officer, who gives his personal skill to special cases. The first-aid dressings are of the simplest character in all cases, in which it is evident that careful examination or operation will be needful at the field hospital. Hemorrhage is arrested by substituting the ligature for the tourniquet, which was applied by the litter squad; bullets, fragments of shell, or other missiles are extracted; fractured bones brought in unsecured are bound up in the best immovable dressings that are available, and tags are buttoned upon those for whom prompt attention of the operating staff of the field hospital is desired. The wounded are then transferred to the ambulances, each of which starts for the hospital as soon as loaded and returns as soon as unloaded, for further service at the front. The ambulance carries two men inside lying down, and one who is able to sit in front with the driver, or four or five inside seated and one lying. The change to the ambulance and thence to the interior of the field hospital does not involve any disturbance of a severely wounded man, for it is the litter, not the patient, that is moved. The litter on which he is first placed forms his mattress on the floor of the ambulance, and his bed when in the field division hospital. Men with flesh wounds not suffering from shock accompany the ambulances on foot, or start for the hospital with a non-commissioned officer of the hospital corps in charge.

It may be observed that the field surgical case of the medical officer is more elaborate than seems called for by the work above indicated. A pocket-case containing a scalpel, bistoury and probe, tenaculum, dressing and artery forceps, silk, needles, and scissors, would suffice, and it is probable that in the field medical equipment of large armies the medical officers assigned to duty at collecting-stations would carry only such a case. In our present service, however, where small commands take the field, the medical officer may have not only to give first aid, but to do all that is needful for his wounded during the days that may elapse before he can transfer them to the post hospital of some permanent station. The light field-case was provided for his necessities. Cavalry commands operating in regions impassable to ambulances carry their medical and surgical supplies on pack animals, and the travois is provided for the transportation of severely wounded men. The travois consists of two strong elastic shafts, each fastened by its front end to the side of the saddle of a mule or horse, the rear ends trailing on the ground nine or ten feet behind the animal. They are kept in proper position, apart from each other, by cross-bars, and the litter is suspended between them. When there is no travois the men of the hospital corps can construct one by cutting suitable poles and lashing on the cross-pieces. This is the Indian method of transporting the disabled.

After a battle the field is searched by the hospital corps for those who have fallen and been obliged to remain on the ground either on account of their disabled condition or by reason of the danger attending any attempt to get away. The conditions under which this duty is performed are exceedingly various, differing perhaps in every engagement, but the first aid brought to the wounded soldier is always prompt and efficient, as above described.

In times of peace the special education of the hospital-corps soldier is carried so far as to enable him to act intelligently when confronted with various accidents and emergencies in the absence of medical supervision. He is thus qualified to enter on a more extensive field of duty than is offered to a litter-bearer on the battle-field. Even in times of peace and slow promotion he is on his way to an acting hospital stewardship, and there are few of our acting stewards who are not looking forward to a steward's position. In case of the expansion of our army for war service this educated body of sanitary soldiers would fill the non-commissioned positions in the corps and permit of its expansion by recruiting merely for the litter-bearer and ambulance companies. For the duties of field service in time of war the education of the litter-bearer in first aid need not be very extensive. The primary management of patients suffering from gunshot wounds is soon learned by intelligent men, and only such should be enlisted for the corps. Moreover, State troops mustered into the service of the United States would bring to the corps their proportion of men more or less trained in army methods. Drill and discipline would soon fit the new men for the work before them and enable the medical department to meet its responsibilities with full assurance of satisfactory results.

Aid given by the hospital-corps soldier on the field of battle or in the accidents of garrison life differs in no respect in its professional details from that furnished by civilians in injuries of a like character. A fractured femur requires the same treatment whether the patient is a soldier run over by a caisson or a laborer by a dray. The aid itself differs from that afforded by competent civilians only in the systematic manner in which it is brought to bear in a given case. The same knowledge of conditions and requirements is needful to the citizen Samaritan and to the sanitary soldier, but the efficiency of the latter is due to his drill and discipline. These, intended to support him in the discharge of his duties when exposed to personal danger, are naturally always sufficient for efficiency when there is no personal danger to distract attention from the care of the injured. When acting officially the efficiency of the soldier is also secured by a judiciously selected equipment which is always on hand for his use. In fact, drill, discipline, and equipment form the tripod by which the efficiency of the hospital corps is sustained and first aid rendered to the injured soldier both in times of peace and in times of war.

Since the accidents of peace among soldiers are so satisfactorily met by these military methods it might be well to inquire to what extent they are or ought to be employed in civil life. This inquiry must, however, be taken up at another time or by some other individual, as it lies beyond the lines prescribed for the present paper.

INSOLATION.

By WILLIAM G. SOMERVILLE, M.D.,

TUSCALOOSA, ALA.

FORMERLY ASSISTANT PHYSICIAN AT ALABAMA BRYCE INSANE HOSPITAL; LATE INTERNE TO ST. CATHARINE'S HOSPITAL, BROOKLYN.

During the summer of 1892, in the months of June and July, there were twenty-two cases of heat-stroke treated in St. Catharine's Hospital, Brooklyn. The majority of the cases reported are from notes taken at the time they were under observation, but in very few could any previous history be obtained. In every case there were cerebral symptoms, which in some were mild, while in others there were symptoms of violent mania, and in others profound coma. In the twenty-two cases under treatment nine were comatose and with high temperature; five had violent maniacal symptoms with high temperature; two had mental confusion, headache, and slight elevation of temperature; four had mental confusion, headache, and normal temperature: two had severe dyspnœa, headache, and normal temperature.

The chief object in the treatment of cases of sunstroke, in which there is an elevation of temperature, is, we believe, to reduce the temperature as rapidly as possible, and this is most readily accomplished by showering the patient freely from head to foot with ice-cold water. The method we adopted in St. Catharine's Hospital was to strip the patient of all clothing and place him on a woven wire bedstead, the head of which was elevated, and beneath the patient was placed a rubber cloth so arranged that the water could run off into a pail. An ordinary sprinkling-pot was used, and the patients freely showered with water as near 32° F. as possible. An ice-cap was applied to the head, and in a few cases the body and extremities were rubbed with ice. The rectal temperature

should be constantly watched, and as soon as it becomes normal the ice-water is discontinued and the patient removed to a dry bed, but in all cases the ice-cap was continued from twenty to forty-eight hours longer. In cases where the temperature was very high, ice-water enemata were given in addition, and in two or three cases antipyrin was given when the temperature had been nearly reduced to normal by ice-water. In the cases with normal temperature the application of the ice-cap was followed by a rapid relief of the headache and confusion. In the two cases with dyspnœa the ice-cap quickly relieved this distressing symptom.

We found that in nearly all of the cases with a very high temperature, the temperature could be reduced to 100° F. in twenty minutes, and to normal in less than an hour. In the maniacal cases it was remarkable to see how quickly they became quiet and recovered consciousness under this treatment. The recovery of many of the cases is due to the ambulance surgeon, Dr. Kirke, who, in the majority of the cases with high temperature, applied ice to them before and during their removal to the hospital, and if the temperature of these cases could have been taken at the time they were found it would in many cases, no doubt, have registered higher. It is of the utmost importance to use prompt treatment in these cases. Two of the four fatal cases were brought to the hospital by the patrol wagon, and no ice used until they reached the hospital.

In those cases with feeble heart-action digitalin and glonoin were given together, and used freely until some effect was obtained. Feeble heart-action was not a contraindication to the use of ice-water. Strychnine and atropine were given when the respiration seemed bad. For the convulsive movements, morphine in $\frac{1}{4}$ gr. doses gave excellent results. The continuous application of cold to the head gave speedy relief to the headache; and its use for from twenty-four to forty-eight-hours seemed to prevent the cerebral disturbances which so often follow severe cases of heat-stroke, as every case of recovery left the hospital without any apparent cerebral disturbance. We append here all the cases treated, some of which were moribund, or nearly so, at the time of their admission. All the cases are males.

Case I.—Aged thirty-eight; laborer; admitted June 13, 1892. Was not removed to hospital until two hours after the onset of attack. On admission rectal temperature 106° F., pulse feeble and rapid, respiration bad, and patient comatose. He was stripped, and ice-bags applied to head and chest, and his entire body showered with ice-water for two and a half hours. Alcohol and glonoin were given hypodermatically, and galvanism applied to the præcordia. After two and one-half hours the temperature was normal, heart-action stronger, and patient would answer questions fairly rationally. He was removed to a dry bed, and ice-cap continued to head for forty-eight hours. There was no subsequent rise of temperature, he became entirely rational, and on June 16th was discharged, recovered.

Case II.—Aged thirty-six; laborer; admitted July 25, 1892. Was exposed to sun all day, and in afternoon felt dizzy and soon afterward became unconscious, remembering nothing until two or three hours after his admission. He was brought to the hospital by the ambulance, and on admission rectal temperature was 106° F., pulse feeble, and there was partial coma. Ice-cap was applied to head, and patient showered from head to foot with ice-water. Temperature was reduced to normal in forty-five minutes. He was put on milk diet, and ice-cap continued. July 26th, rational, but has slight headache and some diarrhœa. Ice-cap continued twenty-four hours longer. July 28th, discharged, recovered.

Case III.[1]—Aged thirty-three; engineer; admitted July 26, 1892. Intemperate in habits, and for several months previous to attack had been treated for gastritis. While working in a heated atmosphere felt some dizziness and muscular weakness, and soon afterward became unconscious. Was brought to hospital by the ambulance, and the surgeon applied ice to him on the way to hospital. On admission rectal temperature 110° F., profound coma, relaxed sphincters, noisy expiration, convulsive movements of arms and legs, heart-action feeble. The ice-cap was put on patient's head, and he was showered with ice-water from head to foot. In forty-five minutes his temperature had been reduced to 100$\frac{3}{5}$° F., and the ice-water was discontinued as his circulation was bad, and respiration was shallow and irregular. He was covered with blankets and given $\frac{1}{60}$ gr. atropine, and three minims of glonoin. Convulsions had ceased, and he would answer questions with slight intelligence. One hour later he became restless and excited, and the rectal temperature was 105$\frac{3}{5}$° F., and there were general convulsions. The ice-water was resumed, and continued three hours. During this time the pulse was 120 and very feeble, and at one time the radial pulse could not be felt, the patient apparently being in articulo mortis. He was given three minims of glonoin and $\frac{1}{60}$ gr. digitalin, after which the pulse became stronger and reduced in frequency. The dose of glonoin and digitalin was repeated after two hours, with further improvement in the heart's action. For the convulsive movements he was given $\frac{1}{4}$ gr. morphia, after which he became quiet. Ten hours after admission he was quiet, fairly rational, and said he felt well; temperature, 99$\frac{1}{5}$° F. The ice-cap was continued on head. He soon slept well, but on the following day was not entirely rational, and was troubled with diarrhœa and vomiting. Temperature on the evening after his admission was 100$\frac{1}{5}$° F., pulse good, and he complained of no headache. July 28th, had much diarrhœa and vomiting. During the evening his temperature rose rapidly, he became restless, boisterous, and excited, with hallucinations and delusions, and at midnight his temperature was 106$\frac{3}{5}$° F., and the arterial tension high. He was immediately stripped and showered with ice-water from head to foot. In one hour his temperature was normal, and he was more rational, but still excitable and talkative. He was given morph. sulph., gr. $\frac{1}{4}$, and atropia, gr. $\frac{1}{100}$. In half an hour he was quiet and sleeping well. On the following day he was quiet and rational, but again troubled with vomiting. He was given peptonized milk and $\frac{1}{8}$ gr. cocaine every three hours. Temperature in the evening was 100$\frac{3}{5}$° F. August 7, 1892, temperature 99° F., troubled some with vomiting, but otherwise doing well and is quite rational. Contrary to our advice, he is removed from hospital by his friends.

Case IV.—Aged thirty-six; pedler; admitted July 26, 1892. On admission was suffering from severe dyspnœa and slight headache, with history of exposure to sun all day. Heart-action feeble, and great prostration; temperature in axilla normal. Inhalation of five minims of amyl nitrite produced no effect. Ice-bag to head and rest in bed were followed by rapid improvement in symptoms. After two hours the dyspnœa and headache were entirely relieved, and on the following day he was feeling as well as ever. Ice-cap was continued twenty-four hours. July 28th, discharged, recovered.

Case V.—Aged eighteen; bartender; admitted July 26, 1892. He suddenly became excited, noisy, and violent, would resist everything. He was found in this condition by the ambulance surgeon, who used ice on him while conveying him to the hospital. On admission he was quiet and rational, and his temperature but little above normal, but his arterial tension was high. Ice-bag was applied to head for twenty-four hours. July 28th, discharged, recovered.

Case VI.—Aged nineteen; baker; admitted July 27, 1892. While walking along the street suddenly became excited, violent, and unconscious, and was found in this state by the ambulance surgeon, who used ice-water on him freely while conveying him to the hospital. He recovered consciousness in the ambulance before reaching the hospital, and on his admission he was quiet; temperature 101$\frac{2}{5}$° F.; there was some confusion, and he com-

[1] Since writing this article we have learned that Case III. died one month after leaving the hospital, with symptoms of gastro-enteritis.

plained of severe headache. Ice water was used from head to foot until temperature was normal, and the ice-cap retained on head thirty six hours. On following morning his mental condition was good, but he had slight headache, which, however, soon disappeared, and he was discharged July 29th, recovered.

Case VII.—Aged sixty-one; coachman; admitted July 29, 1892. When found was in a maniacal condition and would resist everything. He was put in the ambulance and pieces of ice placed next to the body. On admission to hospital rectal temperature was 107° F., heart-action forcible, and arterial tension high; mentally he was quiet, but dull and indifferent. He was showered with ice-water, alternating this with rubbing the body with pieces of ice. After one hour arterial tension was lowered and rectal temperature was 101⅘° F. Ice-water was continued one hour longer, and temperature at this time was 101° F. The ice-water was now discontinued, the ice-cap retained on the head, and he was given grs. xx. antipyrin. His temperature slowly fell to normal, and on following day he felt well and his mental condition was good, excepting some slight mental dulness July 30th, removed by friends.

Case VIII.—Aged sixty; coachman; admitted July 28, 1892. After premonitory symptoms of dizziness and prostration he suddenly became unconscious, and was brought to hospital in ambulance. Ice was applied freely to head and body by the surgeon on his way to the hospital, and the patient recovered consciousness before reaching hospital. On admission, temperature was 106° F., heart-action forcible, arterial tension high, and there was some mental confusion though he was not unconscious, but sphincters were relaxed. He was showered with ice-water from head to foot, and after one hour the ice-water was discontinued as the temperature was normal. He was now given grs. xx. antipyrin and placed in a dry bed. The ice-cap was retained on head forty-eight hours. There was no subsequent rise of temperature, and the patient was discharged, August 1st, recovered.

Case IX.—Aged twenty-one; occupation unknown; admitted July 25, 1892. On admission patient had headache with much mental confusion, and there was some prostration, but his temperature was normal. The application of the ice-bag to the head was followed by prompt relief of all symptoms, and he was discharged, July 26th, recovered.

Case X.—Aged eighteen; occupation unknown; admitted July 25, 1892. When found by the ambulance surgeon the patient was in a maniacal condition, struggling and resisting everything. He was placed in the ambulance and ice-water and ice freely used by the surgeon while conveying him to the hospital. On admission he was quiet, but much confused; rectal temperature was 103½° F. He was showered with ice-water from head to foot, and in half an hour his temperature was normal and he was rational. The ice-cap was applied to his head until his discharge. A few hours after admission he had a severe pain in his right ear, lasting a short time. On the following morning he was mentally clear and feeling well. Taken home by his friends, July 26th, recovered. He was seen three days later and was still doing well

Case XI.—Aged thirty; occupation unknown; admitted July 25, 1892. Was brought to hospital by patrol wagon, and on admission was very maniacal, violent, noisy, and incoherent, with hallucinations of sight and hearing, presenting a typical and classic picture of most violent acute mania. His rectal temperature on admission was 106½° F., heart-action forcible, and arterial tension high. Before obtaining his temperature, in taking which there was much delay on account of his maniacal state, we did not make a diagnosis of heat-stroke, and consequently did not adopt measures for his relief until about one hour after his admission. Four years before admission he had an attack of sunstroke, followed by an attack every year since. For some time previous to present attack he had been very intemperate. When first admitted he was given $\frac{1}{60}$ gr. hyoscyamin without any apparent effect. As soon as temperature could be ascertained the ice-water treatment was commenced, and in twenty minutes there was a marked change for the better in his condition—he became quiet and much more rational; in one hour his temperature was nearly normal, he was perfectly quiet, and conversed rationally about his condition. He was given xx. grs. of antipyrin and the ice-water was discontinued, but the ice-bag retained on head. Nine hours after admission he became delirious, his temperature was 104° F., and the arterial tension high. Ice-water was again used, and the temperature soon reduced to normal, but he did not become as rational as before, and the arterial tension remained high. During the following day his temperature would rise at intervals, but could be readily reduced by ice-water. On the second night after his admission his temperature rose to 105½° F., and he became noisy and incoherent. During the night two $\frac{1}{12}$ gr. and one $\frac{1}{60}$ gr. doses of hyoscyamin were administered, with only a temporary sedative effect. His temperature would rise as soon as the ice-water was discontinued. On the morning of the 27th, the third day of his treatment, venesection was decided upon, and about one pint of blood was withdrawn. Two hours later he spoke quite rationally, and seemed much better, but he soon passed into a condition of low muttering delirium, his pulse became feeble, and he died forty-eight hours after admission. No autopsy could be obtained. There seems but little doubt that this case was a combination of heat-stroke and delirium tremens.

Case XII.—Aged twenty-two; occupation unknown; admitted July 26, 1892, with confusion, prostration, and headache; temperature normal. Ice-bag was applied to head for twenty-four hours, with relief of all symptoms. Discharged, July 26th, recovered.

Case XIII.—Aged twenty-nine; occupation unknown; admitted July 29, 1892, with severe dyspnœa, prostration, and headache. There was no elevation of temperature. The ice-cap was applied to head for twenty hours, and after three hours the dyspnœa was entirely relieved, and on the following day he was feeling entirely well. Discharged, July 30th, recovered.

Case XIV.—Aged twenty-nine; admitted July 29, 1892. He was brought to the hospital by the ambulance, and ice applied during his removal. On admission rectal temperature was 111° F., heart-action very feeble, shallow and irregular respiration, profound coma, tonic and clonic convulsions. By showering with ice-water the temperature was reduced to normal after two hours. Digitalin, atropine, morphia, and glonoin were given hypodermatically. Pulse and respiration would not react to stimulants, and continued bad throughout. Every time the ice-water was discontinued his temperature would rise. There was no return to consciousness, and he died twenty-two hours after admission.

Case XV.—Aged forty-five; baker; admitted July 29, 1892. Was brought in by the ambulance, the surgeon using ice freely during his removal to hospital. On admission temperature was 102½° F. (temperature was taken through a relaxed sphincter, while the patient was lying in ice-water), there was profound coma, general convulsions, sphincters relaxed, respirations irregular, pulse fairly strong. Patient was showered with ice-water. He was given hypodermatically ¼ gr. morphine and $\frac{1}{60}$ gr. atropine, after which the convulsions ceased for a short period and the respirations improved. After an hour and a half this dose was repeated. The ice-water was discontinued after two hours, as the temperature was then normal, and there was a gradual return to consciousness. Four hours after admission he was quite rational, was feeling well, and his temperature continued normal. The ice-cap was continued forty-eight hours. Discharged, August 1st, recovered, without subsequent cerebral symptoms.

Case XVI.—Age unknown; admitted July 30, 1892, with same symptoms as Case XII. Ice-cap was applied

to head for twenty-four hours. Discharged, August 1st, recovered.

Case XVII.—Aged thirty-five; admitted July 30, 1892, with slight rise of temperature, confusion, and headache. The ice-cap was retained on head twenty-four hours, and he was discharged, August 1st, recovered.

Case XVIII.—Aged thirty-eight; was brought to hospital by ambulance, July 30, 1892. Pieces of ice were retained next to surface of body during his removal to the hospital. On admission the rectal temperature was 101⅜° F., pulse fairly good, respiration very shallow and irregular, pupils widely dilated, sphincters relaxed, no conjunctival reflex; coma was profound. Ice-water irrigations were used for a short time; atropine and strychnine were given. After one hour the rectal temperature suddenly dropped to 95½° F., but it was taken fifteen minutes after an ice-water enema, and its accuracy cannot be relied upon. He was immediately placed in a dry bed and hot bottles placed about his body and extremities. After two hours the rectal temperature was 100⅕° F., but there was no improvement in other symptoms. He died fifteen hours after his admission.

Case XIX.—Aged thirty-eight; admitted July 30, 1892. Symptoms and treatment were the same as in Case XII. Discharged, August 1st, recovered.

Case XX.—Aged twenty-two; admitted July 30, 1892. Symptoms and treatment were the same as in Case XVII. Discharged, August 1st, cured.

Case XXI.—Aged twenty-eight; was admitted July 29, 1892, and brought to the hospital by patrol wagon. On admission the rectal temperature was 111° F., sphincters were all relaxed, pupils dilated, and there was complete muscular relaxation and profound coma, pulse rapid and feeble, respiration irregular. He was showered with ice-water from head to foot, the body and extremities were rubbed with ice. Respiratory and cardiac stimulants were given. There was no return to consciousness: the heart-action and respiration did not react to the stimulants. Patient died twelve hours after admission.

Case XXII.—Aged twenty-two; admitted August 10, 1892. When found by the ambulance surgeon he was unconscious, with high arterial tension, and temperature was 102° F. Pieces of ice were immediately applied to the surface of his body, and he was brought to the hospital. On admission his temperature was normal, he was partially conscious, but much confused, and complained of severe headache. The ice-bag was applied to his head for twenty-four hours, and on the following morning he was entirely rational, his mind was clear, and there was no headache. Discharged, August 11, recovered.

NOTE ON THE TREATMENT OF DYSPNŒA IN PULMONARY PHTHISIS BY "ROSIN WEED."

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

All practitioners of medicine are, unfortunately, too familiar with the urgent difficulty of breathing which characterizes at times pulmonary phthisis. Occasionally this oppression accompanies the first stage of the disease; more frequently, of course, it is indicative of its terminal period. Whenever it occurs it is always most painful to the sufferer, and distressing to those who witness it.

I have tried to relieve it, in many cases, by the medicinal or mechanical means ordinarily recommended, with more or less success. I have never found, however, any drug preparation which has given me more satisfaction in its treatment than the tincture of Silphium laciniatum or "rosin weed." This tincture, when taken in half-drachm doses, diluted with a little water, will often give very remarkable relief. And not only will it do this when the pulmonary structure is only partially affected with consolidation, but it will also show its power when the lungs contain many cavities and are infiltrated throughout with tubercular deposits. There are cases, unfortunately, in which silphium produces no apparent good results, and why it is I have not been able definitely to determine, further than to assume that the respiratory centres were incapable of further stimulation. Certainly, increase of bronchitis or occurrence of pneumonia did not always explain the fact. I have never known Silphium laciniatum to do any obvious harm to my patients, although, as I have stated, I have seen it remain without appreciable good effect. My attention was directed to the use of this drug several years ago in a somewhat accidental way, and at first when I wished to procure it, and test its therapeutic properties, I thought I had to do with the Silphium cyrenaicum of the ancients, but I afterward discovered my mistake. For a long while I made experiments with rosin weed both at the New York and St. Luke's Hospitals, and occasionally in private practice, and have been tempted more than once to bring it again before the medical profession. For many facts pertaining to the nature, character, and mode of action of Silphium laciniatum I am indebted to Charles Rice, Ph.D., of New York City, so long and favorably known for his erudition and pharmaceutical knowledge in connection with Bellevue and the city hospitals. Formerly, I wrote for tincture of thapsia in my prescriptions, but, as Dr. Rice informs me, this prescription would incur the liability of an unfortunate and injurious mistake. "For some years back," Dr. Rice writes me, "the only preparation derived from 'thapsia' was a thapsia plaster. This represented the irritating and stimulant rosin obtained from Thapsia garganica L., an umbelliferous plant of North Africa and South Europe. An allied species, Thapsia 'sylphyum' Vivian, also of North Africa, is supposed to be the Silphium (not syl.) cyrenaicum of the ancients. As the first-named species, viz., Thapsia garganica, is more common and is supposed to have the same properties, it has been introduced in place of the latter. In fact, under the name Sylvium cyrenaicum, the Paris drug market sells only the Thapsia garganica. Silphium gummiferum has been applied by Elliott to what is now known as Silphium laciniatum L., or 'rosin weed.' The name chosen by Elliott has long been dropped, but the 'rosin weed' has been used in medicine."

Porcher[1] writes that Dr. H. D. Garrison has reported this plant to be an excellent remedy for asthma. According to Dodd[2] it has been used for the heaves, or asthma in horses. This disease is said not to exist in prairies where the plant grows. King[3] states that the plant is affirmed to be emetic, and to be beneficial in dry, obstinate cough. It is said to be powerfully diuretic. R. O. Thompson[4] also writes that the "plant, Silphium laciniatum (polar or rosin plant) possesses great medicinal qualities. Horses fed upon hay with it intermixed are never known to have the heaves. Cattle, sheep, mules, and horses are extremely fond of the heads of this plant while green, as well as mixed with hay. The pure white resinous gum which it contains performs radical cures in all bronchial cases." It will thus be remarked that, especially among animals, but also among men, this plant is recognized to have valuable medicinal qualities in asthma. I have given it on several occasions with manifest benefit to patients suffering with bronchial asthma. I have not thought it was of advantage in cases of cardiac dyspnœa. I wish to have my observations confirmed or discarded in phthisis, and for this reason would request those who read this communication to make use of the tincture of "rosin weed" and let me know their results. The tincture was made for me at St. Luke's Hospital according to the following formula:

℞. Fl. extr. silph. laciniatum (root) . . . . . f℥j.
Alcoholis . . . . . f℥iv.
Aquæ . . . . . f℥ij.
M. Filter. Sig.: ʒss.–ʒj. as a dose.

In conclusion, I would add that I am surprised to notice how little emphasis certain eminent authorities, like Loomis, Strümpell, Osler, etc., place upon the subjective sensation, "dyspnœa" in advanced phthisis. Personally, I have found it to be a most painful symptom, and one, also, very difficult to relieve. Hence this article. Others, too, like Fagge,[1] write: "Toward the last, orthopnœa is sometimes present in the most extreme degree, the patient gasping for breath, and having the face and hands livid and purple and bathed in sweat." Or Wilson Fox:[2] "It is, however, seldom absent" (referring to dyspnœa) "in the final stages of chronic phthisis, and is commonly, but not constantly, felt whenever bronchitis or intercurrent pneumonia supervene."

THE PROPER FEEDING OF INFANTS.

By FREDERIC M. WARNER, M.D.,

VISITING PHYSICIAN TO CITY HOSPITAL, BLACKWELL'S ISLAND; CONSULTING PHYSICIAN TO FRENCH HOSPITAL (DEPARTMENT OF DISEASES OF CHILDREN), NEW YORK.

THE most frequent cause of the great mortality among young infants is, undoubtedly, imperfect nutrition due to faulty feeding.

Many women give birth to children, and are not able to nourish them; their supply of milk may be either insufficient in quantity or thin and poor in quality.

Often the true state of affairs is overlooked, and the hungry, crying child, supposed to be suffering from colic, is dosed therefor, and the starvation process goes on.

The following case is quite an object-lesson in this connection:

CASE I.—A. B——, healthy child, born at full term, well nourished, and with no inherited disease. After the first couple of days was noticed to cry a great deal and gradual wasting took place. Castor-oil was administered once or twice, followed by green, slimy movements; the trained nurse in attendance reported that the child nursed regularly, and that there was plenty of milk. The ninth day a consultant, who was called in, examined the mother's breasts, and found that although they were large and well developed they yielded only a couple of drops of milk.

A wet-nurse was obtained at once, and the milk pumped out and fed to the child, by means of a medicine-dropper, every few minutes. Stimulants were also administered, but the patient succumbed the following day of exhaustion.

In this case there had been, probably from the first, no milk at all in the mother's breasts. The infant, which at birth was well nourished, was terribly wasted when it died.

The next case demonstrates another class, when the milk, abundant at first, for some cause or other becomes diminished in quantity.

CASE II.—C. D——, well-nourished child, did well until one of the mother's breasts became inflamed, secondary to a sore and fissured nipple. The baby was allowed to nurse on both breasts, but such was the pain caused by the act that the mother permitted the intervals to be as long as possible.

I saw the child for the first time when it was about a month old. It was very much emaciated. It was being nursed very irregularly, every two or four or six hours. It was crying constantly, and was being dosed for colic.

An examination of the mother's breasts showed an almost entire absence of secretion. The patient was at once given artificially digested milk, with stimulants, at regular intervals of an hour each; and in addition was applied to the mother's breasts with the same regularity, with the hope that the mammary secretion might be once more established. A few days, however, showed that we had nothing to expect from the mother.

There were not thirty drops of milk secreted from the time that I saw the case first; but the child did well on the artificial nourishment and made a good recovery.

CASE III.—E. F——, child, was seen on fifth day after birth; it had been crying pretty constantly for the past couple of days; it suddenly stopped and went into a profound sleep; the nurse was supposed to have administered paregoric to it, but she denied this.

On examination the infant was found to be much wasted, and the mother's breasts revealed but a few drops of milk, although the nurse insisted that up to this time there had been a normal amount secreted.

It was impossible to rouse the child by stimulation. A wet-nurse was at once procured, and breast-milk fed the child, by means of a medicine-dropper, every hour at first, and then every hour and a half, day and night, for about a week, the infant gradually coming out of the condition of stupor, and it made a good recovery.

This last case is particularly interesting from the fact that such uncertainty exists regarding the cause of the stupor, whether it was due to an opiate administered by the nurse, or whether it was the collapse of starvation, or a combination of both. The mother, a primipara, thought that the child nursed well, and the monthly nurse was positive that it got plenty of nourishment. At the time that the breasts were examined the absence of milk might be explained as a result of the shock at the child's condition.

CASE IV.—G. H—— was seen as it was dying at about the end of the fourth week. The mother of the child had not been able to nurse it, and it had been fed on one of the infant foods, so called substitutes for mother's milk, with which the market is flooded.

The baby, which was said to have been a fine, fat, healthy one at birth, commenced at about the third week, to give evidences of malassimilation of the food; diarrhœa, vomiting, and rapid wasting took place, until the appearance of the child was that of a living skeleton.

Cathartics were given, as they generally are in these cases, and many other measures tried; everything was done except that which in my opinion would alone have been of avail—the administration of human breast-milk, and the child died literally of starvation.

Comment on these cases is hardly necessary. It may be urged that they are exceptional, that but very few infants run any such danger and risk. I believe, however, that the occurrence is only too common, and that the cause of wasting and emaciation in many cases is due, not to inherited disease, to which it is often improperly ascribed, but to a cause nearer at hand and easier of solution, insufficient and faulty food.

The lesson to be learned from a consideration of these and similar cases is, the administration of proper nourishment, as to quantity, quality, and regularity.

Within five or six hours after birth the child should be applied to the breast, and thereafter every four hours until the secretion of milk is established; this serves the double purpose of exciting the lacteal flow and of drawing out the nipple; and this latter is an important consideration, for the nipple, especially in primipara, may be small and flat, and when later the breast becomes distended with milk—about the third or fourth day—will be on a level with the skin, and therefore a matter of considerable difficulty for the child to lay hold upon. After the milk appears the child should be put to the breast every two hours, and no oftener; it should nurse from twenty to twenty-five minutes. Very young children often remain at the breast only about five minutes and then go to sleep; they should at once be roused by gently rubbing the face and head, and kept awake during the prescribed time. A healthy child will absorb sufficient nourishment from a normally secreting gland during this period.

Too much condemnation cannot be expressed in reference to the matter of permitting the child to nurse when it will, and as much as it fancies, for the following reasons: Too frequent nursing makes the nipples tender and sore; they may become excoriated and lay the foundation

[1] Practice of Medicine, vol. i., p. 974. Philadelphia, 1886

[2] Treatise on Diseases of the Lungs and Pleura, p. 791. London, 1891.

for trouble with the gland itself. Moreover, irregularity in nursing disturbs the child's digestive function; the stomach of the babe, as in the adult, requires a period of rest. This rule is rarely adhered to, and its importance in relation to the good health of the child cannot be over-estimated.

Moreover, an infant which is nursed regularly and about the same duration of time unquestionably absorbs about the same amount of nourishment at successive stated periods; if, on the other hand, a child is allowed to nurse when and how much it will, we have no means of ascertaining the quantity, and must of necessity be uncertain whether the child is getting too little or too much food.

A recent writer has said that it becomes apparent every year that fewer mothers are able to properly nourish their offspring, a statement which I do not believe to be substantiated by facts. I believe that many women whose breasts are dry would have been able to suckle their children had the care and attention been given to the proper application of the child early to the breast, of which a careful consideration of the subject shows the great importance.

The food of the mother the first few weeks after the birth of her child, should consist largely of cow's milk, as much as three or four quarts in the twenty-four hours if possible, and in case of an idiosyncrasy existing whereby the patient cannot drink milk without a great deal of gastro-intestinal irritation, malt preparations, such as ale and porter, may be substituted, supplemented by nourishing soups and underdone beef and mutton, with cereals and vegetables; in other words, a full diet.

If a careful examination of the breasts from day to day reveals the fact that they are not secreting sufficient milk to sustain the child, the problem is presented whether it is of use to persevere in nursing the child, or whether other measures should be employed.

Emphatically I insist that the child should be put to the mother's breast every two hours, allowed to nurse all the milk therein contained, then fed a quantity of cow's milk which has been predigested, a sufficient amount, to be determined by the physician in attendance. This is easily done by gauging the flow from the breasts, and giving of the artificially digested milk enough to supply the deficiency. In this connection a valuable aid in determining whether the child is being sufficiently nourished will be found by weighing the infant daily.

In case ample trial convinces the physician that the mother has no breast-milk, one of two measures may be employed; preferably, if the patents can afford the expense, a wet-nurse should at once be secured; on the other hand, we have the uncertain means of feeding the child with artificially digested food, cow's milk, peptonized, which, to say the least, is hazardous with city-bred children.

66 West Fifty-sixth Street.

The Medical Profession in California.—There are 2,531 physicians in active practice in California to-day; of these 354 are homœopaths and 267 eclectics, leaving 1,910 regularly qualified physicians. This gives us about one doctor to every 530 inhabitants—quite enough. "The Register" shows that there are 143 illegal practitioners. To this number we could add about 1,000 quacks—men and women—who are in the "healing business." These are about equally divided into "spirit-healers," Christian science doctors, faith-curers, magnetic and clairvoyant frauds, to say nothing of tape-worm "professors," "face-ironers," and "beauty" specialists.

Sneezing for Hysteria.—The idea has been suggested that in certain well-known conditions of hysteria a judiciously administered pinch of snuff might have a beneficial effect. Familiar to everyone is the perverseness with which such hysterical attacks resist ordinary remedies, and it seems not improbable that some of them might be curtailed by a period of vigorous sneezing.

Clinical Department.

PURULENT OPHTHALMIA, FROM THE STANDPOINT OF ITS SPECIFIC MICROBIC CAUSE.

With a Plea for a more Energetic, Rational, Abortive Treatment where Possible.

By ALFRED HINDE, M.D.,

Chicago, Ill.

Senior Surgeon Eye and Ear Department, Central Free Dispensary; Ophthalmologist to the Neurological Clinic, and Assistant to the Chair of Ophthalmology to Rush Medical College, Chicago.

The following are the conclusions of an article read before the Ophthalmic Section of the American Medical Association, at Milwaukee, Wis., June, 1893:

1. That all cases of purulent conjunctivitis are of microbic origin and due to Neisser's gonococcus.

2. That all cases originate from a gonorrhœal focus, by devious paths, often, but not always, traceable.

3. That those parts of the conjunctival sac having a cylindrical, or a modified cylindrical epithelium, viz., the palpebral portions and that of the fornices, are the seats of election of the micro-organism.

4. That the location of the gonococcus on the mucous membrane is, at first, super-epithelial, then inter-epithelial; and still later sub-epithelial, and all combined.

5. That its special habitat is within the pus-cell, yet it is also extra-cellular as well as intra-epithelial.

6. That the associated inflammation of the adjacent lid-tissues is due to the lymphatic absorption of the ptomaïnes of the microbe.

7. That the compact stratified epithelial layer of the scleral conjunctiva and cornea is very resistant to the attack of the gonococcus.

8. That ocular complications are due to pressure necrosis, producing an infection atrium through which the streptococcus, and maybe the staphylococcus, find ready entrance to tissues with greatly impaired physiological resistance, and often rapidly destroy them, resulting in perforation of the cornea, intra-ocular infection, and loss of the eye. This is a secondary infection.

9. That the therapeutical indication is the mechanical removal or destruction of the gonococcus, with its ptomaïne, and that if this is done early and thoroughly in the weeping stage, the period of acute inflammation will be cut short and the ocular complications avoided.

10. That it is well in the incubative stage, even without positive evidence of a gonorrhœal origin, to regard with suspicion all cases of severe monocular catarrh, and especially so in the female, irrespective of age or condition, and to treat them as if due to the gonococcus.

11. That the mechanical removal of the discharges and the loosened epithelia, and therewith the microbe and its ptomaïne, by thorough brushing of the palpebral conjunctiva and that of the fornices, and ample flushing of the conjunctival sac with simple diluents, or weak microbicide solutions, fulfils the etiological indication and is non-injurious in all severe cases of simple catarrhal conjunctivitis.

12. That of all local remedies nitrate of silver is the most potent, and, at the same time, least irritating microbicide we possess. It prevents complications, and can be used in sufficient strength to destroy the gonococci without risk of injury to intact ocular tissues, and that solutions of greater strength than two per cent. are unnecessary.

13. That in cases when first seen, where complications already exist, brushing of the palpebro-fornix conjunction should be resorted to, with thorough frequent irrigation of the conjunctival sac, preferably with sublimate solutions up to 1 to 5,000. If undue lid-pressure exists free canthotomy is advisable, but scarification of the serofibrino-plastic chemosis of the scleral conjunctiva does not relieve exudative pressure on the ocular tissues, and it opens the doorway for secondary infection with pus microbes and is a dangerous proceeding.

14. Where the cornea alone is inflamed, the added, guarded daily use of a bichloride solution, 1 to 500, to the infected area, is the best treatment, together with myotics, not on account of the latter's mycotic action, but because, after a preliminary increase, they reduce intra-ocular tension by contracting the blood-vessels and diminishing serous exudation, and thereby they improve the nutrition of the ulcerated, softened, corneal tissues. Paracentesis of the anterior chamber through the bottom of the ulcer is called for only in those cases where perforation impends, or where positive, progressive intra-ocular infection exists.

15. The use of a mydriatic is best limited to those complicated cases where the uveal tissues are threatened or inflamed, because after a preliminary reduction it increases intra-ocular tension by impeding the outflow of fluids from the eyeball, thus resulting in increased posterior pressure on the softened cornea, impairing nutrition and aiding bulging.

16. A supportive compress-bandage is antiphlogistic and of great use in preventing staphylomatous results in complicated corneæ, and its use ought to be continued until the healed cornea is again unyielding.

17. Ice-cold applications check microbic multiplication and ought to be used assiduously to the end of the acute stage, or until ocular complications ensue. After the latter occur applications as hot as can be borne are more comfortable and more conducive to the improvement of the nutrition of the impaired ocular tissues.

18. As a prophylactic in monocular cases the other eye ought to be sealed against infection; and the risks to others from these cases thoroughly advertised.

19. The treatment of the initial focus of infection, when ascertainable in the infected subject, must be rigidly carried out on the same lines, and simultaneously with the conjunctival inflammation.

16 Laflin Street.

THERAPEUTICS OF RESORCIN.

By JAMES ALLEN PATTERSON, M.D.,

SALEM, N. J.

Resorcin is a well-known crystalline substance, colorless, odorless, and of a sweetish acrid taste, freely soluble in water, solutions changing from their original colorless appearance to that of a reddish brown upon standing twenty-four to forty-eight hours; the color gradually deepening in tint as time elapses, caused presumably by its oxidation, the discoloration apparently in nowise injuring the therapeutic activity of the drug in solutions a week or two old.

Resorcin, "as now obtained, being a derivative of phenol" ("Wood's Therapeutics"), partakes of the physiological and toxic properties of that group. Internally an overdose induces flushings of the face, giddiness, tinnitus aurium, disturbances of the circulation and of respiration, followed by collapse. The urine becomes charged with the greenish-black substance similar to that found from the toxic effects of carbolic acid.

Locally it is a caustic in strong solutions, medicinal strengths (two to ten per cent.) possessing the power of arresting processes of fermentation. Upon mucous membranes and abraded surfaces it possesses local anæsthetic effects of a very high degree of efficacy; in fact, the antifermentative and local anæsthetic effects of the drug are the only ones that have proved sufficiently valuable, in my experience, to give the drug a place in the physician's armamentarium, its use as an antipyretic being unsafe in the large doses required for such effects, even then being inferior to the various "antis" in vogue. As a remedy used locally by spray to the pharynx and larynx it has become my sheet-anchor in pertussis and allied spasmodic affections of the larynx and bronchi. I have recently encountered a violent epidemic of whooping-cough, having treated cases in which the constant hacking had produced such extreme irritability of the stomach that food could not be retained, thus inducing loss of flesh and strength, combined with changes in the lung-substance (emphysema and lobular collapses and infiltrations) and damage to the cardiac valves, producing dyspnœa, insomnia, and great general bodily discomfort, together with intense head-pains from the constantly recurring shocks of the cough; frequently the patients were found not only confined to the house but bedridden. Many, being adults, were most heartly disgusted mortals.

After beginning the use of resorcin in the manner to be related, reduction in the frequency and severity of the cough paroxysms was quickly noticed. This causative element being eliminated, the remaining symptoms fell in the line of march toward recovery; of course, some instances of permanent damage to the lungs and heart have remained. Many came under my care after having suffered three to six weeks. All cases seen in the early stages where this treatment was instituted were not aborted, as some authorities claim,[1] but the attacks were lessened in severity and shortened in duration very materially, no complications being encountered. I believe its action in pertussis to be largely that of a local anæsthetic, as the lessening of the excessive sensibility of the pharyngeal and laryngeal mucous membrane prevents cough; though I would not discountenance the fact that the bactericidal effect of resorcin may kill the microbus morbi.

My manner of adminstration has been by spray. The few instances in which I tried it by stomach administration proved failures. I use a five to ten per cent. aqueous solution, by a long, straight-tubed atomizer into the pharynx every one or two hours. Being thrown with sufficient force the spray rebounds from the posterior wall of the pharynx upon the epiglottis and the parts beneath it. In obstinate cases the same solution can be thrown into the larynx and, with proper precautions, into the trachea. This spray is equally applicable to the hard, dry cough of old bronchitics, and if used with sufficient persistence will lessen the emphysematous tendency toward which these cases constantly progress.

As a calmative in tubercular laryngitis it has proved with me more satisfactory than cocaine. A case I have in mind in which the disease ultimately proved fatal: the patient having become adept in the use of the atomizer, was able to obtain great relief from a spray directed into the larynx through a tube bent downward for that purpose. Its use before eating would greatly facilitate her ability to swallow, and used at other times would alleviate the pains of the disease. Upon two occasions, without her knowledge, I changed the resorcin solution to that of cocaine. She immediately detected the difference and begged for the original formula. In hay fever, as a nasal application, I have not obtained the relief expected from its efficient action in the pharynx. My technique may be at fault.

In chronic gastritis, particularly of infants and of the aged, it has been a boon, being particularly applicable to those artificially fed infants of rickety tendencies, who digest badly, suffer from the discomforts of flatus, both gastric and intestinal, and constipation, in consequence of which they are peevish and sleepless in the extreme. I always administer it to them in watery solutions, upon an empty stomach, in doses of one-quarter to one grain, for children whose ages range between three and twelve months, one-half to one hour before feeding; it will thus be repeated every two to three hours. It has the advantage of being tasteless, and can thus be readily exhibited by spoon, or, as I frequently suggest, by allowing the child to suck the prescribed dose from a wineglass through its nursing-nipple with tube attached. In these cases it may be advantageously combined with the phosphate of soda, proper regulation of diet, of course, being indicated.

My experience in adults coincides in general with those of Thompson.[2] Suffice it to say that it has acted the most favorably in the chronic gastritis of old alcoholics. It has appeared to act as well in three- as in five-grain doses.

Locally, in skin affections it is an established dermatological formula, in chronic eczema and psoriasis, where a stimulating application is indicated in exudative thickenings.

PROCIDENTIA UTERI IN A PREGNANT WOMAN.

By AARON JEFFERY, M.D.,

BRADFORD, VA.

I REPORT this case on account of its rarity, and also to show what a pregnant woman *may* undergo without having a miscarriage.

I was called to see Mrs. V——, a German by birth, aged thirty-six years, mother of two children, on June 6, 1892. I found her with complete procidentia of the uterus, the womb having been out for a week, so she said. The labia and uterus were very much swollen and inflamed, having a muco-purulent discharge. There was also a bloody discharge mixed with mucus from the os uteri.

The uterus was very tender and painful, and as she suspected that she was pregnant I decided to have consultation before taking any steps in the matter. Dr. R. B. James saw the case in consultation with me, and we both thought it improbable for her to be pregnant. We accordingly replaced the uterus at once, and kept it in position with absorbent-cotton balls, saturated in equal parts of glycerine and extract of white pinus canadensis. After keeping her in bed for a week, and daily replacing the cotton balls, she was able to walk about without protrusion of the uterus. Before I saw her she had been doing general house-work, carrying water and coal, cooking, etc. I was surprised when her husband saw me in October and engaged me to attend her during her confinement, which he thought would be in a month or two.

Shortly afterward I was taken with typhoid fever, and Dr. W. A. Willson delivered her of a healthy, full-term boy, on January 14, 1893. At this time she is in better health than she has been for a year or more, and thinks she is again pregnant.

A CASE OF POISONING FROM AN OVERDOSE OF CODEINE.

By WILLIAM PHILIP SPRATLING, M.D.,

NEW YORK.

SHORTLY after ten o'clock on the evening of June 8th I was requested to see a young married woman who had taken an overdose of codeine. Immediately after dinner, about 7 o'clock in the evening, she had taken sixteen half-grain pills, making eight grains altogether. She had suffered for some months from a painful disease, and had been ordered by her physician to take codeine in quarter-grain doses for the relief of pain, and to overcome a persistent insomnia. Not deeming the quarter-grain pills of sufficient strength, the patient then procured from the druggist a vial labelled as containing one hundred half-grain codeine pills. Three hours before my visit she had swallowed sixteen of these, as she avowed, for the purpose of securing a good night's sleep. An hour later she experienced considerable nausea, and vomited a small quantity of semi-liquid matter. I found her awake, able to converse perfectly well, but extremely restless and irritable. She could not lie in one position, but constantly changed it by tossing, almost violently, from side to side of the bed. At frequent intervals she would manifest convulsive movements involving the entire voluntary muscular system. These movements were most marked in the upper extremities and the head. She suffered greatly from intense irritation of the skin over the entire body. This irritation was most annoying along the flexor surfaces of the forearms and on the back. She had an attendant rub her back so vigorously with a coarse towel that the skin in many places was broken. The surface of the body was warm and dry. The pupils were fixed in pin-point contraction. Respirations were twelve per minute. She complained of great thirst, and an uncomfortable feeling of fulness in the head. I endeavored to ascertain by repeated questioning whether she experienced any of the pleasant mental effects that follow the exhibition of morphine, but failed to find that such was the case with her at any time during the action of the drug. She frequently remarked that her "thoughts were going round and round." After the painful irritation of the skin had been relieved by sponging the body with solution of bicarbonate of soda, she sank into a light doze, from which she would awake in a few minutes with a start. The skin was hyperæsthetic to a marked degree. She was subjected to the usual treatment for opium-poisoning, and in a few hours was much improved.

By noon on the following day she had fully recovered from the effects of the drug in every way, save that considerable muscular weakness remained. We apparently have no fairly accurate knowledge as to what amount of this drug may be regarded as a fatal dose. In the latest edition of "Wood's Therapeutics" it is stated that "Robiquet in a series of experiments found that doses of 0.01 to 0.03 gm. (0.15 to 0.46 gr.) produced a feeling of contentment, calmed nervousness, and induced refreshing sleep; while 0.1 to 0.2 gm. (1.53 to 3.07 gr.) caused deep sleep followed by nausea and vomiting." Quoting further from the same author, he adds, "Dr. A. S. Myrtle[1] records a case of serious poisoning by four grains of codeine." And Dr. D. Walsh[2] reports serious poisoning by eight grains of codeine.

IMPERFORATE HYMEN — RETAINED MENSTRUAL FLUID.

By CHAS. E. NAMMACK, M.D.,

VISITING PHYSICIAN GOUVERNEUR HOSPITAL, NEW YORK.

SOPHIE P——, aged eighteen, native of Poland, was brought by ambulance, at 2 P.M., May 24, 1893. No one at the hospital understanding her native tongue, her previous history could not be obtained. That she was suffering intense pain and had an abdominal median tumor extending upward to the umbilicus, were very evident facts, and the house-surgeon, on attempting vaginal examination, discovered that the hymen was imperforate, the labia separated to the extent of two inches, and the perineum bulging as if by a fœtal head.

It appeared to me, from the girl's general robust development, that she should have menstruated at least two years previously, and I reasoned that the changes in the uterus and Fallopian tubes during that period would render immediate evacuation of all the retained fluid dangerous. The vaginal distention was so great that she was unable to urinate, nor could a catheter be passed. Aspiration of the vagina was accordingly ordered, and a sufficient quantity of the retained fluid withdrawn to make her comfortable and allow the urine to be withdrawn by catheter. The aspiration puncture was not sealed, but through it the accumulated menstrual discharge was allowed to escape guttatim.

The next day the visiting surgeons were invited to see the case, and Dr. J. E. Kelly of the visiting staff, at my request, incised the thickened hymen under strict antiseptic precautions, evacuated the retained fluid, and irrigated the cavities with a one-half per cent. creolin solution.

The patient made a speedy and satisfactory recovery. The case seems to show that the danger formerly attributed to rapid evacuation of these accumulations can be obviated by asepsis.

New York, July 15, 1893.

THE PATHOLOGY OF NERVOUS DISEASE.

IN a paper published in a recent issue of the *Boston Medical and Surgical Journal*, Dr. Charles L. Dana takes up the question of modern pathology in its bearing on the pathology of nervous disease, adding some therapeutical deductions in regard to the use of organic extracts. The author, who styles himself an amateur in general pathology, suggests that the present is rather too exclusively the day of the clinician and of the anatomist, and that it would be an improvement to try to learn, if possible, the actual and primary causes of nervous disease. No reason can be given why muscular atrophies should be progressive, or shaking palsies should forever shake. Perhaps they always will; yet there is no reason to suppose it, and every patient should furnish a field of earnest effort until the mystery of the disease is solved.

Leaving out tumors, mechanical injuries, and rupture or stoppage of blood-vessels, organic nervous diseases may all be classed as inflammatory or degenerative. Inflammation is best described teleologically: it is the reaction of the system to a poison or irritant. The irritant is a toxine, and in most cases the product of a microbe. The part of the system which reacts to the irritant is derived from the mesoblast; in other words, it is connective tissue and blood-vessels. Animals without a mesoblast do not have inflammation. When the irritant consists only of dead cells, as occurs after aseptic injury, there is a reparative process; but in the other forms the irritation is of a microbic, or perhaps sometimes of a diathetic, origin. It acts especially upon the blood-vessels, connective tissue, and lymphatics, and it calls into play the defensive cells (phagocytes) and defensive proteids (socin and phylloxin) of the body. There is always present a something which may be called positive chemotaxis, and which sets the organism into active warfare against the invader. It is not of so much importance what the exact cellular changes are; the point is that there can be no inflammation without a cause, and that this cause is a poison of microbic origin usually, and of chemotaxic power. Different microbes call out the defensive powers of mesoblastic cells and defensive proteids in different degrees. The parenchymatous cell, or in this case the nerve-cell, has no defensive powers of its own, and has to rely on the mesoblast—perhaps in some instances upon the epiblastic neuroglia—for its protection. Besides inflammation, there are certain changes in the nervous system which are called primary degenerations, such as locomotor ataxia and the progressive spinal myopathies, in which the nerve-cell dies first, as though starved or under the influence of a narcotic poison. The cells die, and as they cannot die without a cause, one must conclude that here, too, there is a toxæmia.

The relation of syphilis to tabes suggests that this cause is sometimes of microbic origin. The toxine in degeneration, however, does not cause vascular or connective-tissue irritation. There is repulsion, a negative chemotaxis, and death.

The writer suggests that the matter may be put succinctly in this way: There is in inflammation a positive chemotaxis, and in degeneration a negative chemotaxis, both conditions being due to some toxic principle of extrinsic or intrinsic origin. And he then proceeds to apply these views—which are in the main established doctrines in general pathology—to special classes of nervous diseases. Alcoholic meningitis, so called, he finds to present post mortem no signs of inflammation, but only signs of congestion, anæmia, and œdema, not sufficient to account for all the symptoms. It is, in reality, a condition of brain-poisoning. Post-mortem evidences of tubercular meningitis in children frequently consist only of intensely red meninges and a few tubercles, though during life marked tubercular symptoms may have existed. Death here is not due to an inflammation, but to an overwhelming poison, or toxæmia. Dr. Dana denies that acute primary myelitis ever occurs except from septic infection. This view is supported by Oppenheim, of Berlin, who has hardly found a case; Leyden takes the opposite position. How, we are asked, can there be an acute primary myelitis, except from sepsis or tubercular or syphilitic foci? Acute exudative and destructive inflammation elsewhere does not pick out a section of the organ it invades. It is easier to suppose that in most cases of so-called acute myelitis, there is first a ruptured vessel, or an obliteration through spasm or thrombosis, and that the injured part simply undergoes repair; or, as sometimes happens, becomes secondarily infected or inflamed. Chronic transverse myelitis is generally admitted to be rarely, if ever, a primary affection. Most cases are the sequelæ of an acute process, of syphilitic disease, or of traumatism. By rigid and more appropriate use of the word inflammation, present phlogistic conceptions of nervous disease become modified and replaced by the words toxæmia, necrosis, and degeneration. There are certain chronic neuroses, of which paralysis agitans is one, in which post-mortems show that there has been for a long time a continual irritation of the connective tissue and blood-vessels, with secondary cellular disturbances. Such conditions answer to the definition of a chronic inflammation. Assuming paralysis agitans to be of the nature of a chronic inflammatory irritation, one must infer that there is a cause for it, and that this cause is toxic, and further that paralysis agitans is a chronic toxic disorder.

In ordinary Sydenham chorea, the consensus of opinion attributes its nature to disturbances of the same character; the evidence shows that the original trouble is humoral or microbic in origin, and that the anatomical changes partake of a subinflammatory character. The theory that epilepsy is a toxic disease, propounded by the late Dr. Austin Flint, is, no doubt, in part the true one. A toxine resulting from some defective metabolism or

glandular activity, may be the active factor in producing neuroglia-sclerosis, and convulsions. The degenerative state existing in most cases of idiopathic epilepsy, may find its expression quite as much in a defective tissue change as in a purely defective condition of the nerve-cells. Idiopathic epilepsy may be best explained as a disease of the whole body, and not simply a disease of the cortex of the brain. Many nervous diseases must be regarded as of glandular or metabolic, as well as of nervous, origin. Nerve-centres defective in power of resistance to the attack of extrinsic or intrinsic agencies acting injuriously upon the system, yield readily to the power of an intoxicant. Weakening effects, as powerful emotion, lessen the resistant powers of the entire organism. They render especially susceptible those particular parts that received inadequate endowment in the beginning. In this way may be explained how fright will set up a paralysis agitans, or a neurasthenia, or an exophthalmic goître. The point to bear in mind is the importance of regarding many of the nervous diseases, not as scleroses, or degenerations, or inflammations, or congestions, but as the result of some ulterior factor, and that it is which one desires most actively to attack. How to do it is as yet uncertain; the author of the paper suggests the application of new methods of dealing with infectious diseases—the use of the ferments, immunizing serum, extracts of normal tissues and organs, and antitoxines, from whatever source they can be obtained.

FOURTH OF JULY SURGERY.

The accidents in this city attendant upon the celebration of our late glorious Fourth were numerous, and make an interesting contribution to surgery and contemporaneous history; the total number reported was forty-one, which makes exactly one case of surgery to every fifty thousand of the population, assuming that all cases were reported.

The favorite form of surgical celebration appears to have been a burn: there were seventeen cases of this kind of injury. Following very closely upon burns came gunshot wounds, of which there were seventeen. All parts of the body were perforated, but the lower limbs were in the majority, receiving eight shots, while the arms received four, the chest two, and the head three. No citizen of New York is reported to have been shot in the back. One person, we regret to say, was killed accidentally by a rifleshot, one was thrown from a wagon, one had his leg fractured, and two received lacerated wounds.

We extend to the forty unfortunates our sincere commiseration. Fourth of July will come again, and another forty will be hurt, perhaps fifty. For there are two millions of people who escaped, and they must still have their celebration. Mr. Pope touched at the explanation when he said: "I never knew a man in my life who could not bear another's misfortune perfectly like a Christian." The unscathed millions are sorry, but they bear up, and buy more fire-crackers.

St. John's Guild.—Judge Ingraham, of the Supreme Court, has rendered a decision awarding St. John's Guild $10,000 of the $100,000 which Mrs. Elizabeth Fogg left on her death, in 1890, to be distributed among ten different charitable institutions.

PROPOSED NATIONAL BUREAU OF HEALTH.

In another column the Committee of the New York Academy of Medicine submit a first draft of a Bill establishing a National Bureau of Health. As success in securing the passage of any bill must depend upon the concentrated efforts of all interested in such legislation upon a single measure, the Committee has wisely submitted to public criticism a plan of organizing a central health bureau, with a view of obtaining such information as will enable it to mature a bill which will, as far as possible, be generally acceptable and approved. The plan of creating sanitary divisions of the United States, and having a central commission composed of representatives from each division, is a new and important feature, and is quite in accordance with our form of government. The manner in which the co-operation of State Boards of Health is secured is worthy of consideration, as also the creation of an executive committee composed of local members with the President of the Commission. By this latter arrangement there would be an intelligent and efficient, but inexpensive, body at the capital, so situated that it would be practically always in session. The plan proposed seems to us to embody many excellent features, and we trust that it will receive wide publication by the medical press, and such consideration by the profession as will enable the Committee to formulate a bill which will be accepted heartily by all who are interested in securing a competent branch of sanitary administration in the General Government.

ALCOHOL IN DISEASE.

Much is being made of a report by Dr. B. W. Richardson on the non-use of alcohol in the treatment of disease. Dr. Richardson treated about two hundred cases without employing any C_2H_5HO, these cases including pneumonia with emphysema, 5; acute pneumonia, 7; lobar pneumonia, 4; broncho-pneumonia, 3; double pneumonia, 1; alcoholic pneumonia, 1; other diseases of the respiratory organs, 34; of the organs of circulation, 23; of the digestive organs, 34; of the nervous system, 14; of the urinary system, 4; of the uterine system, 13; rheumatic diseases, 27; enteric fever, 5; poisoning, 5; miscellaneous diseases, 24. The general results recorded of these two hundred cases are thus given: recovered, 116, or 58 per cent.; relieved, 44, or 22 per cent.; unrelieved, 11, or 55 per cent.; died, 29, or 14.5 per cent.

Among the pneumonias, of which the total number was 13, the mortality was 5, or over one-third. The general mortality of the hospital was 6.2 per cent.; that of the medical side, 11.6 per cent. while the hydrate of ethyl was not used at all, Dr. Richardson seems quite partial to O_3, NH_3, H_2O_2, $C_5H_{11}NO_2$, and other recondite chemicals. It seems a little odd that a hospital should be founded for the purpose of excluding the use of hydrate of ethyl while permitting all other forms of stimulating and sedative compounds. Nor does it seem that the results of treatment in any way justify the therapeutical position taken.

The Will of Edwin Booth leaves the sum of $5,000 to the Home of Incurables at West Farms.

News of the Week.

Arsenic and Cholera.—A monthly publication called *The Arena*, which aspires to deal with the larger problems of existence, publishes an article on "Arsenic *vs.* Cholera." "By so taking arsenic," says the writer, "we fix the albumin to such an extent that cholera (which does the same) cannot take hold, and thus cause, along with the loss of the salts, the cramps of the disease. By taking arsenic by mouth, hypodermically, or from ivory points, and repeating as necessary to produce this effect we destroy the animal and vegetable germs extant at the time of the exhibition of the remedy, and preserve the tissues from further and rapid carbonization in consequence thereof; and as it is a reconstructive as well as a tonic, we obtain immunity from the comma bacillus as long as forty days thereafter, making each person so arsenicized a non-infected and non-infectant medium daily growing stronger."

A critic in the *British Medical Journal* adds: "Voltaire somewhere says that magical incantations will kill a flock of sheep if a sufficiently large dose of arsenic be given at the same time; on the other hand, we have little doubt that arsenic will often protect from cholera—if assisted by a sufficiently lively faith." It is astonishing that editors of lay journals can be so deficient in prudence and intelligence as to allow such doctrines as we have quoted to be published.

The Cholera.—Under date of July 1st *The Lancet* gives the following account of the prevalence of cholera. There is not much to be added of a very satisfactory or reassuring character to our report of last week. Cholera seems to be widely distributed at the present time, although, if we except Mecca, it has not manifested itself with epidemic strength or severity at any particular place. In Europe it has been generally mild in form but persistent in character. At Mecca, however, the outbreak has been very severe and is still increasing with alarming rapidity. The deaths on June 25th numbered 455, and later reached even 1,000 a day. During the first ten days of last month 62,000 pilgrims passed through Jeddah alone, and further arrivals are still announced. As regards France, cases of cholera have occurred in the northwest, west, and south of that country, and the disease seems to have been widely distributed. The health of Paris keeps good, but not so that of other parts of France. For some time past cholera prevailed to a limited extent in Brittany, especially at Lorient and Quimper, and subsequently the disease appeared in Southern France. Cases of cholera, with the usual proportion of deaths, have occurred at Nimes, Montpellier, Cette, Bessèges, Frontignan, Alais, Lyons, Toulon, Nantes, Hyères, and Marseilles. The disease is extending southeastward to the frontier of Spain. The valley of Andorra in general has suffered, and at Pamiers, in the Arriège department, the visitation is said to have been severe. Nantes in the west is affected, with a prospect of the disease extending up the valley of the Loire, and there are rumors of suspicious cases of choleraic disease at Bordeaux. According to a telegram from Paris of June 28th, it is reported from Carcassone that an outbreak of cholera, which is attributed to the bad water, has occurred in the village of Luc-sur-Aude, where out of 200 inhabitants, 12 deaths have been registered and 15 cases are under treatment. The people have fled from the commune. Fresh cases are reported from Hyères and Seyne.

Telegrams from St. Petersburg, dated July 12th, report that the city has been officially declared to be in a healthy condition. Fifty medical men who had been detained at the military academy for fear that there would be an outbreak of cholera have been dismissed to their homes. The last weekly official report on the epidemic in Russia gives the following figures for the provinces where the disease prevails: Podolia, 310 new cases, 100 deaths; Bessarabia, 35 new cases, 15 deaths; Orel, 32 new cases, 12 deaths; Kherson, 18 new cases, 9 deaths; Toula, 8 new cases, 3 deaths. From Budapest the news comes that true Asiatic cholera prevails in Hungary to a slight extent, the prompt measures taken by the government having prevented thus far any alarming spread of the disease. There has been an average of two cases daily. The number of deaths, if there have been any, has not been reported. Eighty-five cases of cholera are reported in the hospital at Alexandria, Egypt. Forty deaths from the disease have occurred. There were five new cases of cholera and four deaths from the disease in Toulon during the twenty-four hours, ending July 12th.

Dr. James J. Levick, of Philadelphia, died June 25th, of heart disease, aged sixty-eight. He was graduated from the University of Pennsylvania in 1847, and became a resident physician in the Pennsylvania Hospital, and subsequently one of the attending physicians. At a later date Dr. Levick was elected to the staff of Wills Eye Hospital. He was also connected with the Magdalene Asylum. In 1884 he received the degree of Master of Arts from Haverford College.

To Inspect Coming Immigrants.—Surgeon-General Wyman, of the Marine Hospital Service, has ordered Surgeon Fairfax Irwin from Marseilles to London, to report to the Consul General there, and to have charge of all the inspections made at London, including the emigrant station at Blackwall, on the Thames, from which emigrants leave for Southampton. There are two inspection physicians already employed by the Consul General at London, and they will hereafter be under the direction of Surgeon Irwin, and all bills of health will be signed by him.

Surgeon W. J. Stimson has been ordered to Glasgow to have charge of all the inspections at that port.

The Long-pending Suit of Dr. Charles E. Simmons against the executors of the estate of Samuel J. Tilden, has been settled out of court. Dr. Simmons sued for $143,350 for professional attendance upon Mr. Tilden, from September, 1878, to August, 1886.

A compromise was effected a few days ago, and Dr. Simmons receives $40,000 for his eight years of professional attendance upon Mr. Tilden.

An Appeal is Issued to American Jews to assist in establishing a hospital in Jerusalem for American Jews. Funds are to be sent to the Society of Ezrath Cholim, Jerusalem, Syria.

Dr. J. B. Hamilton has been appointed editor of the *Journal of the American Medical Association.*

University Extension, as we understand the scheme, is an educational system by which the services of expert teachers are utilized for persons who are not able to connect themselves with universities. The giving of University Extension lectures in a university is a good deal like preaching to the heathen from a home pulpit. We notice, however, that the University of Pennsylvania has extended its work so as to include Extension. Drs. J. S. Billings and A. C. Abbott will give a course of lectures on hygiene.

Medical Legislation in Connecticut.—Connecticut, too, has fallen into the line of medical progress. Its State Legislature has recently passed a bill providing for the appointment by the State Board of Health of three Examining Committees, each to consist of five physicians selected by the Connecticut Medical Society, The Connecticut Homeopathic Medical Society, and the Connecticut Eclectic Medical Association, respectively. Each committee is to frame its own questions and conduct its examinations in writing, and both questions and answers are to be placed on file with the State Board of Health. Applicants for the privilege to practice need but be graduates of medical colleges that are recognized as reputable by any one of the chartered medical societies of the State. The license confers the privilege to treat, operate, prescribe, or practise surgery or midwifery "only in the kind or branch of practice as stated in the certificate of registration."

Obesity and Life Insurance.—Dr. Kirsch has studied the question of obesity in connection with life insurance. Ordinary obesity is not a reason for refusing a policy. If obesity is hereditary, if in the family history there has been diabetes mellitus or cerebral hemorrhage, the medical expert should be cautious. If obesity is extreme the heart and urine should be carefully examined. Irregular pulse and bradycardia are bad signs. When intemperance coincides with obesity the probability of long life is small.

Treatment of Cholera Infantum.—Cross, of New York (*Therap. Monatsh.*, May, 1893), who states that an exceptionally large number of cases of infantile cholera come under his notice, claims to have successfully combatted this disease: first, by hygienic and dietetic measures; secondly, only by drugs. Children showing marked pyrexia attended by convulsions, but as yet no other symptoms, are subjected to a rectal irrigation of cold water, and friction with alcohol in iced water. If necessary, small doses of antipyrin are frequently administered, and should the patient then have overcome the acute onset, a strict diet is enforced, to commence twenty-four hours after the attack, all milk being excluded, regardless of the child's age. On the other hand, thin gruel, boiled sugar water, or tea are given frequently in small quantities, and salt-water irrigations are administered once in twelve hours, while six minute calomel powders are given at two-hourly intervals. By these means the attack is cut short, and in twenty-four hours milk from the breast or otherwise can be given with impunity. Should, on the other hand, the malady be developed, the abstinence from milk should be longer, the injections should be made more frequently, and a sufficiency of fresh air in or out of doors must be enjoined. In addition, calomel and salol, or the latter only in the later stages, are frequently administered, and during recovery hydrochloric acid and pepsine are substituted. Obstinate cases which have lapsed into a chronic condition are relieved by weak tannic-acid injections, and continuous vomiting generally yields to flushing of the stomach once daily with weak hydrochloric acid, one operation generally sufficing. Should the child be first seen in a collapsed condition, the author recommends immediate warm irrigation of the stomach and rectum with hot mustard baths, and small quantities of stimulants, as even the most serious cases often improve under energetic action.

A Criticism of Koch's Bacteriological Diagnosis of Cholera.—The meeting of the Berliner Medizinische Gesellschaft on June 21st was more than usually interesting by reason of a paper read by Professor Oscar Liebreich, entitled "Critical Remarks on the Methods of Examining Cholera Excreta." The gist of the paper was that Koch's methods cannot lay claim to the reliability in cholera diagnosis which is claimed for them. One by one the methods of examination as taught and practised by Koch and his followers, namely, the microscopic method, the culture method, the animal experiment method, and the cholera red reaction, were subjected to severe criticism, and clear proof of the insufficiency of all these methods was advanced. Liebreich, though he yields to none in his conviction of the importance of bacteriological research, nevertheless feels it imperative to make a stand against uncalled-for enthusiasm and hasty conclusions. He dwelt on the mistaken modern tendency to seek the source of cholera exclusively in external causes, ignoring Virchow's researches on the cell as the element which, by losing its power of resistance, predisposes to disease.

Mortality in New York.—The number of deaths in the city during the quarter was 11,844, and the death rate 25.37, lower than for three of the preceding four years. There were 3,958 marriages and 12,265 births. There were 342 more male children born than female children, but this preponderance is much more than offset by the greater number of deaths among male children. There were more than a thousand more deaths of males than of females. Less than one-third of the number of children born were born of native parents. Of the men to marry 486 were widowers, and of the women 411 were widows. The deaths of unmarried males exceeded the deaths of unmarried females by over a thousand. Over five hundred more married men died than married women, and over four hundred more widows than widowers.

Typhus in New York City.—From January 1st, to April 1st, the last quarter, there were 328 cases of typhus fever in New York City. Of the victims 316 were men and only 12 women. One hundred and eighty-one were between the ages of twenty-five and forty-five. One hundred and nineteen died. Owing to the large number of cases reported, and with the view of stamping out the spread of the disease, the Board of Health on January 5, 1893, appointed thirty assistant medical sanitary inspectors to visit all of the lodging-houses of the city once every twenty-four hours, between the hours of 10 P.M. and 2 A.M., to note the temperature of the rooms occupied as sleeping apartments, and, if over 68° F., to

order better ventilation. The wisdom of this determination is proved by the fact that sixty-nine cases have been found by these doctors and the sufferers removed to the hospital in the early stage of the disease. This surveillance over the lodging-houses and their occupants still continues, and will not be abated until the close of summer.

An Offer to Mind-readers.—Professor G. Ponchet has offered 1,000 francs to any one who can read a single word known only to himself and enclosed in a sealed envelope. The medium can have an hour to try, and if he fails must pay 25 francs, which sum will be bestowed on the poor.

Dr. S. Pozzi, of Paris, has been commissioned by the French Ministry to proceed to the United States and to study the organization and installation of surgical laboratories, instruments used in the practice of surgery, as well as general questions of the teaching of medicine and surgery.

Professor Adam Politzer, of Vienna, has been appointed by the Austrian Cultus-Minister, a scientific delegate to the Medical and Hygienic Exhibition, to be held at Chicago in connection with the World's Fair.

Dr. A. M. Makejew, late Professor of Midwifery in the University of Moscow, has bequeathed 200,000 roubles ($100,000) for the erection of a church in connection with the various clinics of that University.

Impending Resignation of Professor Henoch.—Professor Henoch, Director of the Clinic of Children's Diseases in the Charité Hospital, Berlin, has intimated his intention of resigning his chair at the end of the current semester. Professor Henoch, whose name is known throughout the medical world as the author of a standard treatise on the diseases of children, is seventy-three years of age, and has held his present appointment for forty-three years. The names of Professor Kohts, of Strassburg; Soltmann, of Breslau; and Heubner, of Leipzig, are mentioned in connection with the chair which will be left vacant by Professor Henoch's retirement.

The Gunning Prize.—The Victoria Jubilee Cullen Prize, of the value of $500, given every third year by Dr. Gunning for the most important contribution to practical medicine, has just been awarded to Dr. William Russell, Assistant Physician to the Royal Infirmary, Edinburgh, for his work on the etiology of cancer and for the stimulus his work has given to investigations in that field.

Mr. Ernest Hart on the Constitution of the American Medical Association.—Writing to the *British Medical Journal*, Mr. Hart says: The weak point which I laid my finger on, was the evanescent character of the membership, which then depended upon annual delegation from the respective State Societies, which are the constituent bodies, corresponding in that respect, but differing in others, from our Branches. There are still, however, some other defects of organization, which I think could easily be remedied, but which hinder the growth of the American Medical Association. On some of these I have been in consultation with members of the executive and have been asked to renew them in writing; they were meantime received with approval. The system of election of the governing body is capricious, and does not provide for stable and complete representation, but leaves room for much canvassing and wire pulling, and by its elaborate incoherence raises opportunities for side issues and local contests quite irrelevant to the true objects of the Association. Some of the principles which at present govern the selection of matter for the *Journal* and the conduct of its editorial department are incompatible with the high scientific, professional, and literary attractions which it ought and might easily be made to present. All this might be altered without additional expense for the moment, and the *Journal* be made to serve the best interests of the Association and the profession, and to add largely to its resources, which could then be available for making its pages yet more attractive, so that it would—like the *British Medical Journal*—be the chief recruiting agent for the Association. This position, it is acknowledged on all hands, it does not at present occupy, faithfully and ably as it has been edited by Dr. Culbertson and his distinguished predecessors, among whom Dr. N. S. Davis, the founder of the Association, holds an honored place. My suggestions bear chiefly on the transference of the power of election of the governing body from the "fortuitous concurrence of atoms"—as it has been described in our columns by a correspondent—called a "general meeting" to the county societies, who are the constituent bodies, and who should therefore be the elective power. From these representatives should be constituted the sub-committees for detailed work, who should act under and be governed by its authority. There are at present more than one separate controlling committee of "trustees," of "judicial action," of "nomination," etc., who act independently of each other, and are constituted hurriedly and by caucus influence at the general meeting—a system which might well injure any society, and which has more than once provoked deplorable and painfully mischievous schisms. It speaks highly for the inherent and unquenchable vitality of the principle of the Association—"broad based upon the people's will"—and of the vigorous love of the profession and the Association which actuates the most respected members, that the Association has ridden successfully through all such storms. It survives and develops, but with maimed vitality, throughout the year, and without that powerful influence on public affairs and professional progress which it might derive from better constituted committees of government, and of public and parliamentary administration, and from a more attractive and effective voice and tongue in its *Journal*. In saying this I speak of new things, and with none but the most appreciative and respectful spirit. The meeting was large and much of the work was first-rate.

An Epileptic Canary.—M. Féré tells us (Société de Biologie, June 8th) that epilepsy is not unfrequently met with among birds. Hitherto, however, only two such examples have been recorded in detail. M. Féré has recently had under observation a canary thus affected. The attack commenced suddenly with a kind of aura, the bird extending its wings. This movement was followed immediately by a turning of the head to one side and then the animal fell. Generalized tonic spasms were then succeeded by clonic spasms, these stages being followed by a period of stupidity, often accompanied by impulsive acts.

American Medical Association.

Forty-fourth Annual Meeting, held in Milwaukee, Wis., June 6, 7, 8, and 9, 1893.

(Special Report by Telegraph to the MEDICAL RECORD.)

(Continued from p. 58.)

SECTION ON SURGERY.

THIRD DAY, THURSDAY, JUNE 8TH.

Tumors of the Neck.—DR. W. L. RODMAN, of Louisville, read a paper on this subject. The deep cervical fascia plays an important part in tumors of the neck, sometimes preventing deep tumors from appearing superficially for years. It is for this reason that congenital tumors may appear only in adult life. The author reviewed concisely and clearly the various kinds of tumors, cystic and solid, with their diagnosis and treatment. Bronchoceles should be excised if possible; so also should multilocular cysts, but their numerous adhesions render this often a serious undertaking.

Partial thyroidectomy is indicated for thyroid cysts, as complete thyroidectomy is invariably followed by myxœdema.

The author has met with two cases in the adult where a circumscribed swelling of the sternomastoid muscle simulated a solid tumor. This is much more frequent in infants, especially after a breech delivery.

Unless seen very early, malignant tumors of the neck are not operable, as an elimination of the disease would require too great a loss of tissues. Surgery also promises but little in lymphadenoma.

In tubercular glands of the neck the submaxiliary are always the ones first affected, followed by the occipital, the subclavian, and later the deep glands. The best treatment is the total extirpation of the glands and their capsules, *en masse* if possible. A temporary section of the sternomastoid muscle is of great benefit in this operation. If not extirpated, the glands remain as a constant source of danger to the individual.

In the discussion of the paper DR. MACLEAN expressed surprise that excision of hydrocele of the neck should be preferred to tapping and injecting iodine, which had met with universal success at his hands.

DR. MUDD expressed a doubt as to the invariable sequence of myxœdema upon complete thyroidectomy in this country, where we are free from the taint of cretinism. He has performed complete thyroidectomy several times and has seen no signs of myxœdema in his cases.

Nephrectomy or Nephrotomy.—DR. JOSEPH PRICE, of Philadelphia, in discussing this question said that incision and drainage of the kidney are no more dangerous than the same procedure elsewhere in the body. In pyonephrosis the danger lies in delay. The importance of accurate diagnosis is therefore seen. Aspiration of the kidney is not to be lightly undertaken for diagnostic purposes, as the field is large and the chance of hitting the right spot is small. Owing to the greater mortality in nephrectomy, and to the difficulty of exactly determining the condition and the power of adaptability of the other kidney, and also because of his belief that all kidney tissue which has any secreting power should be spared, the author advises nephrotomy rather than nephrectomy wherever the more radical operation is not clearly indicated.

Surgery of the Ureter.—DR. W. VAN HOOK, of Chicago, presented a communication on this subject. Until recently, he said, accidental injuries to the ureter in laparotomies have been considered irremediable, and the kidney has been extirpated primarily or secondarily. The author has devised a method of uniting the severed ureter so that no stenosis follows. The cut end of the cystic portion is closed by a ligature, and a longitudinal incision made just below the ligature. The end of the renal portion is slit up a little, and the whole lower end is introduced into the longitudinal incision by means of a double leading thread, and is held there by passing the threads through the walls of the cystic portion a little below, and knotting them on the outside. No suturing is necessary. The author calls this lateral implantation.

If the section is near the bladder, the renal end is brought to the abdominal surface to drain, and the bladder is also brought up and stitched to the abdominal wall as high up as possible.

Later, after the firm fixation of the bladder in this position, the ureter is inserted into the bladder; or if it is not quite long enough, a new ureter can be made by a plastic operation on the bladder-wall.

The insertion of the cut ureter into the rectum is primarily dangerous, and also frequently leads to ureteritis, owing to the difference in the physiological conditions of the two mucous membranes. So pyonephrosis is a secondary danger, and has almost always resulted in the author's experiments upon dogs.

After reviewing the methods of other surgeons in the treatment of section of the ureter the author maintained that nephrectomy for that cause alone was no longer justifiable.

Radical Treatment of Hernia.—DR. H. O. MARCY, of Boston, presented an analysis of one hundred and thirty-three cases of hernia operated on for the purpose of radical cure. In the author's one hundred and thirty-three cases there were no deaths; there were six recurrences, although in over one-third ten years have elapsed since operation. In only one has a truss ever been worn since operation. Attention was again called to the excellency of the kangaroo-gut for buried suture. Dr. Coby, of New York, has had fifty successive cases of primary union with its use.

The author believes that the normal relations of the parts should be restored as far as possible in the operation, and thinks there is too much disturbance of anatomical relations in Halsted's method.

Aneurism of the Femoral Artery.—DR. DONALD MCLEAN, of Detroit, reported two cases of aneurism of the common femoral artery, treated by ligature of external iliac. Both cases were traumatic, one from a bullet-wound, the other from a knife-stab. The ordinary surgical rule of cutting down and ligating above and below is too dangerous in aneurisms of this artery. Ligating the external iliac artery was easily accomplished in both cases and the results were perfect, with no sign of recurrence of the aneurism.

Establishment and Maintenance of a Urethra above the Symphysis Pubis in Chronic Prostatic Obstruction.—D. J. HAYES, of Milwaukee, showed one case of this nature and cited another where the operation had afforded immense relief. The patients have voluntary control of the bladder, and are able to hold water five hours. The bladder empties itself completely. The operation performed was a Hunter Maguire's—a suprapubic cystotomy, with a withdrawal of the tube in three days, and the sinus kept open by the insertion of a miniature steel sound.

In the discussion DR. MAGUIRE said he had performed the operation sixty-five times, with only two deaths, both from pre-existing pyelo-nephritis.

Rupture of the Small Intestine.—DR. H. C. DALTON, of St. Louis, reported three cases of traumatic rupture of the small intestine, with operation. In the first case operation was delayed until the second day, and resulted fatally. The other two cases were operated on the first day and the result was successful.

The diagnosis is of course, the important point. Faintness, shock, paroxysmal pain, pain on pressure, tympanites, nausea, and vomiting are the important symptoms. If, in spite of rest for several hours, the paroxysmal pain and the vomiting continue, a laparotomy is strongly indicated.

Ureterectomy.—DR. H. A. KELLY, of Baltimore, said that ureterectomy is the removal of a part or whole of

the ureter. It is bad surgery to remove a diseased kidney and leave behind a diseased ureter; the two should be removed together. The author reported a successful case of nephro-uterectomy for primary tuberculosis of one ureter with secondary extension to the kidney.

The diagnosis was made by catheterizing both ureters and analyzing the urine so obtained. Pictures and diagrams were shown of a new method of reaching the kidney and ureter retroperitoneally, the incision being more lateral than usual.

FOURTH DAY, FRIDAY, JUNE 9TH.

A New Treatment of Hernia was the title of a paper read by DR. ALEXANDER DALLAS, of New York. The writer said that there were three and one-half millions of herniæ in this country, eighty per cent. of which were inguinal. This shows the importance of the lesion, especially to general practitioners, who should understand its treatment better than they do. Skilful palliative treatment is almost always successful in childhood.

The author has devised a new truss which meets the indications necessary better than any existing truss. It is a light steel spring, arching over and supported by the crest of the ileum, and held in place by a single transverse strap. The posterior pad rests upon the sacrum, the anterior one is hollowed and presses downward over the internal ring. The truss is not worn in bed, but a home-made bandage is applied in the few cases where any appliance is necessary. Massage and electricity are also used to promote the strength of the muscles forming the rings. The success by this method has been pronounced. The author condemns the turning over the palliative treatment to instrument-makers.

He showed, also, a new instrument for the operation of radical cure, when it becomes necessary. The instrument is inserted into the canal, and on being withdrawn scarifies the walls of the canal, insuring a more firm union. The patients are kept in bed only four or five days, and wear his truss for three or four months longer.

The author further suggested that strangulated hernia would often yield to extremely gentle taxis after the subcutaneous injection of morphine and atropine, and the exhibition of warm drinks, including strychnia and digitalis. The proper position of the patient is necessary. Failing in extremely gentle taxis one should then immediately resort to the knife, an anæsthetic being unneedful, and indeed harmful, owing to increased shock and subsequent vomiting.

End-to-End Suture of the Intestine.—DR. E. A. TAPPEY, of Detroit, reported a case of successful end-to-end suturing of the intestine. It was a secondary union of the small intestine, subsequent to a primary formation of an artificial anus for strangulated hernia. Convalescence was rapid and uneventful. Although somewhat fearful of the foreign-body element in the Murphy-button method, the writer intends to use it at the next opportunity.

In discussion DR. MURPHY said that he felt absolutely confident that no harm would follow from the button as a foreign body. In gunshot wounds of the intestine, if multiple perforations existed, they were generally in proximity, and two feet of the intestine could be resected, including all the perforations, with the use of a single button, and without necessarily evil results.

DR. GASTON reported the successful removal of thirty inches of small intestine, the silver suture being used.

A New Applicator for Introducing Medicaments into the Urethra, Uterus, and Rectum, was shown by DR. A. B. KIRKPATRICK, of Philadelphia. The instrument was first shown at a local society meeting in 1881, and has met with great success since then. It is a hollow tube with a piston-rod, and by its use pencils of powder can be lodged at the affected portion. There are three sizes of tubes, fitting the calibre of the urethra, uterus, and rectum.

In gonorrhœa the author uses a pencil of powder consisting of equal parts of iodoform and boric acid, and he reported four cases to show the excellent results of such treatment.

A New Method of Treatment of Strictures of the Rectum.—DR. J. B. BACON, of Chicago, read a paper with this title. The author's method is to build an entirely new channel around the connective tissue of the stricture, and is only made possible by the use of the Murphy button. After laparotomy in Trendelenburg's position the sigmoid flexure is united to the rectum below the stricture by means of the Murphy button, one part of which is inserted in the sigmoid flexure and held by a loop stitch, the other part being inserted through the anus by the assistant and pushed through a small incision in the rectum; no suture is possible.

The loop of flexure and rectum between the points of this union is made to adhere together by means of scarification and a few stitches. After the button comes away, from the sixth to the fifteenth day, a long pair of forceps is inserted through the anus, one jaw passing through the artificial channel, the other through the stenosis of the rectum. The forceps are closed, having in their grasp one side of the stricture and the septum of the loop formed by the anastomosis. The forceps come away in a few days, bringing with them part of the stricture and septum, and leaving behind a fair-sized rectum. If the stricture is a low one and it is doubtful whether the sigmoid flexure can be made to reach below it, the rectum can be exposed by Kraske's method, and the upper part of the rectum can be brought down and anastomosed instead of the sigmoid flexure. The further procedure is the same as above stated.

By this method a cure results, and, the sphincters being preserved, incontinence of fæces is avoided. Post-mortem specimens from operations successfully performed on dogs were shown to the Section.

A New Material for Surgical Splints and Jackets, with the Method of Its Application.—DR. E. A. TRACEY, of Boston, has prepared wood-pulp so that it successfully meets all the indications necessary in a splint material. It comes in sheets, can be cut into the necessary shapes, and when moistened becomes plastic. When held in place by a bandage it soon dries. If desirable it can be covered with silicate of potash to render it stiffer and keep it cleaner.

NEW YORK STATE MEDICAL ASSOCIATION, FIFTH DISTRICT BRANCH.

Ninth Annual Meeting, held in Brooklyn, May 23, 1893.

THE morning session was principally occupied by the address of the president, DR. S. B. WYLIE MCLEOD, the business of the Branch, and biographical sketches of Fellows deceased during the past year.

Chloroform in 1893.—The only scientific paper was one by DR. EDWARD R. SQUIBB, on "Chloroform in 1893." In it he presented the latest facts in regard to the use of chloroform as an anæsthetic, and stated that even when this agent was administered in the purest form and with the utmost precaution a certain number of deaths would occur which were attributable solely to the potency of the drug itself. A larger proportion, probably one-half of the deaths caused by chloroform, were due to cardiac syncope. The sooner that the fact of its unavoidable danger was generally accepted, the sooner, he said, would the profession be united in adopting a safer anæsthetic. He had found by personal observation that the ether which was employed in England was of a very impure character and therefore highly objectionable, and he believed that this was one reason why the English surgeons were so prejudiced against the use of this agent.

The Prevention of Blindness from Ophthalmia Neonatorum.—At the afternoon session the first paper was by DR. L. H. W. ALLEMAN, on this subject. While complete antisepsis of the birth-canal was very desirable, he said, it was almost impracticable to secure, and therefore

the simplest plan was to treat the eyes of the new-born child. He urged the general adoption of the method of Credé, who advised dropping into the eyes, after the lids had been thoroughly cleansed, a two per cent. solution of nitrate of silver. He thought it criminal to neglect some such precaution in any case that was at all suspicious, and while it might perhaps often be unnecessary in private practice, he believed it would be of great service to adopt it as a routine measure. If it should be thought that a two per cent. solution was too irritating, a one per cent. solution of nitrate of silver might be employed. Up to the present time ophthalmia neonatorum constituted the cause of blindness in a very large percentage of cases; but as small-pox had been practically eliminated as a cause of blindness since vaccination had been generally adopted, so this could be if a proper feeling could be created on the subject in the minds of the community. Among the poorer classes, mothers did not at all appreciate the danger attending their babies' sore eyes. In discussing the paper Dr. T. H. Burchard stated that the number of cases of ophthalmia neonatorum in his venereal service at Charity Hospital, on Blackwell's Island, had been reduced from about forty-five per cent. to one per cent., by enforcing scrupulous antisepsis of the mother's vagina and external genitals before and during delivery. Dr. Coffin having remarked that in his opinion nitrate of silver was too irritating to the infant's eyes, and might of itself possibly be a cause of ophthalmia, Dr. Squibb pointed out the fact that the crystallized nitrate of silver is an acid salt, so that any solution made from it would cause a greater amount of irritation than one made from the fused nitrate of silver (lunar caustic), which was entirely free from acid.

Chronic Nasal Catarrh, and what the General Practitioner Can Do for It.—Dr. Edward J. Birmingham read a paper on this subject. He thought that on account of the extreme frequency of chronic nasal catarrh, which was to be regarded not as a disease, but as a symptom of various pathological conditions, every physician should have some practical knowledge of rhinology. In order to diagnosticate and successfully treat ordinary cases very little apparatus was required, and anyone by devoting a little attention to the subject could readily acquire all the skill that was necessary in making examinations and in the application of remedies. In case any condition were present which required operative procedures the general practitioner would thus be enabled to detect the trouble and send the patient to a specialist, and if this were not the case he would be fully competent to conduct the treatment himself. The ordinary nasal douches, he said, were apt to prove injurious, and it was equally injurious to forcibly inject fluid into the nasal cavity. As a substitute he exhibited a convenient douche, by means of which fluid was made to pass gently through the passages merely by gravity. He also explained the method of using sprays and insufflations, anteriorly and posteriorly. As an alkaline and antiseptic agent, he had found glyco-thymoline a most admirable preparation, and he had also found a solution of iodoform and tannin in ether (which left the iodoform and tannin deposited upon the mucous membrane) extremely efficacious. For insufflation stearate of zinc was one of the most useful remedies, and in atrophic catarrh the use of Reichard's ventral oil had been attended with good results in his hands. In conclusion, he spoke of the necessity of judicious constitutional treatment in connection with local measures, and incidentally remarked that if any permanent benefit was to be expected it was essential that the patient should entirely give up smoking, if he were addicted to the habit.

The Treatment of Certain Forms of Fracture.—Dr. Charles Phelps then read a paper with this title. Among those referred to were fracture of the vault of the cranium, in which he strongly recommended early trephining, which he regarded as often of great service in the prevention of subsequent trouble. In fracture of the patella he said that his recent experience had only served to confirm his opinion of the great superiority of the method of wiring the fragments together. In this way he had in all cases been enabled to secure perfect osseous union, and without a single drop of pus forming in the joint. In his later practice he had entirely abandoned the use of strong antiseptic solutions (now employing a bichloride solution of the strength of only 1 to 20,000), and he had become more and more convinced of the utility of skilled massage as an adjuvant in the treatment. The plan of subcutaneous suture he considered radically defective, as it never secured osseous union. In Colles' fracture he had found that the mistake was commonly made by surgeons of having the splints too long. In ununited fractures he considered the methods of drilling and of resecting and wiring the ends of the fragments the most satisfactory, and the former of these was usually preferable.

The last paper was one by Dr. H. B. Judson, on "The Management of Hip Disease."

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 12, 1893.

H. P. Loomis, M.D., President, in the Chair.

Round-Cell Sarcoma of the Thigh.—Dr. F. Ferguson presented a tumor which had been removed from the thigh of a German stone-cutter, thirty-one years of age. His work necessitated frequent pressure on his thighs. About two years ago he first noticed a small, hard lump, which since then had slowly increased in size. The specimen was found to consist of a mass of soft tissue, partly fibrous and partly muscular, and a spindle-shaped tumor, 6 ctm. long and 4 ctm. in its largest transverse diameter. The interior had undergone extensive degeneration, and externally there was an ill-defined fibrous capsule. A section of this tumor under the microscope showed extensive areas of small round cells, supported by a fairly regular stroma of fibrous tissue. There were many areas of degeneration, and the vascular supply was rather scanty. Many slides had been stained for tubercle bacilli, but none were found.

Dr. T. M. Prudden said that notwithstanding the peculiarities presented by the specimen, he considered it one of small, round-cell sarcoma. The lack of blood-vessels might, perhaps, account for the areas of necrosis present.

Cerebral Thrombosis Simulating Cerebral Apoplexy.—Dr. Ferguson then presented a brain, taken from an Italian, forty-eight years of age. He had only very recently come to this country, and no history of previous illness could be obtained from his friends. He was admitted to the New York Hospital House of Relief, on April 9th, and it was stated at that time that at 5 A.M., while at his residence, he had had a convulsion. When found by the ambulance surgeon there was complete hemiplegia on the right side, and he was unable to articulate, but was partially conscious. He had one convulsion soon after his admission, and another on the following morning, in which he died. On admission his temperature was 99° F., that afternoon it was 98.6°, and on the next morning, prior to his death, the temperature reached 100.6°.

The autopsy revealed congestion of all his organs, especially the lungs and kidneys. The left hemisphere of the brain was generally softened; the occipital and temporo-sphenoidal lobes of this side were quite soft, and contained innumerable punctate hemorrhages. There was also a firm thrombus in the internal carotid and middle cerebral arteries on the left side. The thrombus was composed of small round cells, blood, and fibrine. In the examinations made the vessels containing the thrombus were found normal. The vessels of the pia on both sides were also normal. Fragments of the thrombus were carefully stained for micro-organisms with a negative result. These examinations will be pushed still further and a report made at some future time.

Dr. Ferguson said that some time ago he saw a case of cerebral softening without the presence of a thrombus. Here the lumen of the middle cerebral artery was found to be considerably obstructed by an endarteritis. This partial obstruction, increased in all probability by muscular contraction of the remainder of the wall, had so diminished the arterial supply to the brain as to give rise to the softening. In another case, a woman, while lifting a heavy wash-boiler, suddenly fell down, and death occurred within forty-eight hours, with all the usual symptoms of cerebral apoplexy. Post-mortem examination in her case showed a thrombus in the internal carotid and middle cerebral arteries, without any lesion of the arteries or of the heart.

Dr. Prudden suggested that it would be well to avoid the use of such vague terms as apoplexy; it would be much more definite to speak of cerebral hemorrhage, cerebral thrombosis, and cerebral embolism, when these conditions actually exist.

An Extremely Large Tubercular Kidney.—Dr. A. T. Weston exhibited a very large tubercular kidney, which had been removed from a woman, aged thirty-seven, who gave a general history of tuberculosis dating back to when she was five years of age. She had had fairly good health up to last November, at which time she was seen by Dr. J. L. Hopkins, who found a tumor much smaller than the present specimen. It extended from the brim of the pelvis up to about the fifth rib, and filled both thorax and abdomen, extending beyond the median line to the right. The urine contained a small quantity of albumin and some casts. The principal symptoms for three or four weeks previous to her death were intense nausea, vomiting, and severe pain. At the autopsy the lungs were found to contain cavities and cheesy nodules; the liver was large, soft, and yellow; the stomach was sacculated, owing to pressure of the tumor; the other kidney was normal.

Dr. Ferguson said he had examined the tumor, and found at one or two points on the periphery of this multilocular cyst a few kidney tubules. The ureter was completely occluded by inflammatory material. Scrapings from the interior of the cyst, when stained, showed innumerable tubercle bacilli. This was the largest tubercular kidney he had seen.

Dr. George P. Biggs said that he had examined some sections at the periphery, and had found typical tubercular tissue.

Abdomino-peritoneal Pregnancy.—Dr. Albert C. Stanard, present by invitation, exhibited a specimen of what he supposed to be an abdomino-peritoneal pregnancy. He had removed this specimen by operation from a woman, twenty-three years of age, who had been married five years, and had had one child about a year after her marriage. About six months after this she contracted a gonorrhœa, which lasted for eight months. About last August she began to complain of headache and backache, but menstruation continued, and she had none of the usual symptoms of pregnancy. On November 13th the menstrual flow was rather more profuse than usual. On December 17th, as a result of unusual excitement and effort, she was seized with sudden pain and uterine hemorrhage, and for the next month there was a variable flow of blood, and considerable pain in the right iliac and sacral regions. When first seen by the speaker, on March 1st, there was a tumor occupying almost all of the true pelvis, and the uterus was enlarged to about three times the normal size. Cœliotomy was performed, and the Fallopian tube on the right side was found to lie across the top of the tumor, with its end adherent to it. The adhesions were separated and the tumor removed with the tube and ovary. The fimbriated extremity of the tube is just within the wall of the tumor. The tumor was globular in shape, measured about four inches in diameter, and was filled with clots. An examination by a careful pathologist had failed to show any remains of gestation. He thought it possible that gestation had existed from August to December, and that then the fœtus was killed, and since that time had undergone absorption.

Dr. S. T. Armstrong doubted very much if entire absorption of the products of gestation could occur in so short a time. It was more probable that the case was one of salpingitis, and that a hemorrhagic effusion had occurred at the period mentioned.

The President agreed with the preceding speaker that the time was too short for entire absorption to have occurred.

Dr. Ferguson remarked that the general appearance of the interior of the cyst resembled that of a gestation sac.

Empyema and Sub-diaphragmatic Abscess.—Dr. E. Le Fevre reported a case which came to him about one month ago. The patient was twenty-five years of age, and had been well up to about one year before, at which time he had an attack of "the grip." About four months later he was suddenly seized while at work with a severe pain in the lower part of the left side of the thorax, accompanied by very severe cardiac palpitation. He was carried home, and remained in bed for about three weeks, and during this time he lost about thirty pounds in weight, and had severe chills, with some pain in the chest, but the expectoration was scanty and not blood-stained. Suddenly his breath became offensive, and within a few hours there was a gush of offensive pus. From this time on there was an abundant fetid expectoration, but no bacilli were found in it. At the first examination, from the angle of the scapula to the base of the lungs there was flatness on percussion, loss of vocal fremitus, and an entire absence of all voice-sounds. When seen the next day there was amphoric breathing all over this side. Subsequently Dr. H. P. Loomis, having found pus with an aspirating needle, inserted a drainage-tube.

The President said he had considered the case one of pyo-pneumothorax. A long needle was inserted just below the angle of the scapula and at various other points, without drawing pus, but finally on inserting the needle high up between the scapula and the vertebral column, pus was obtained, and a pint and a half was then drawn off with the aspirator. The patient improved for about one week, when it became necessary to secure drainage, and a tube was inserted into the pleural cavity near the diaphragm. The sputum became scanty and less offensive, but the patient's general condition was not improved, and he died finally of exhaustion.

Dr. Warren Coleman said that as he had made the autopsy he would present the specimen and describe in detail the pathological condition.

The right lung was removed without difficulty, and was normal. The upper lobe of the left lung was free, but the lower was bound down to the outer and posterior chest-wall and to the diaphragm. While trying to break up the adhesions a gush of pus was noticed to come from under the left lobe of the liver. On lifting up the diaphragm on this side, an opening was found leading into the pleural cavity. The finger could be passed through this opening and made to protrude through the chest-wall where the drainage-tube had been inserted. A portion of the left lower lobe was cut off, and left attached to the diaphragm. The upper lobe of this lung was found to be normal, and the lower completely atelectatic. No pus was discovered in the lung nor in the pleural cavity, and no part of the lung was gangrenous. On attempting to remove the spleen, a fresh gush of pus was observed, so the liver, diaphragm, stomach, and spleen were removed as a whole. Several small abscesses were found between the liver and the lesser curvature of the stomach, but not involving the structure of either organ. An abscess about two and a half inches long and one inch wide was found externally on the spleen. On the upper surface of the left lobe of the liver, between it and the diaphragm, was another abscess of about the same size, but not involving either organ. The largest abscess of all was bounded above by the left lobe of the liver, to the left by the spleen, and below by the stomach.

It had not involved any of these organs except the spleen. On the surface was a pyogenic membrane. The pus had a sickening, gangrenous odor. Communication of the cavity with the opening in the diaphragm was established through the ulcerated upper portion of the spleen.

Dr. George Biggs said that, as it was very rare for pus to originate below the diaphragm and extend upward into the chest unless the suppurative process were distinctly connected with the organs in that location, it was more probable that in the case just reported the abscess formed in the chest. This theory was strengthened by the fact that the sub-phrenic adhesions were of comparatively recent formation.

Carbolic-acid Poisoning.—Dr. George P. Biggs exhibited a stomach, showing a very extensive eschar on the mucous membrane, as a result of carbolic-acid poisoning. The eschar was white and leathery, and involved chiefly the œsophageal end and the fundus, although quite marked around the pylorus. Strange to say, the patient's lips, mouth, and œsophagus showed scarcely any traces of the corrosive action of the acid.

Partial Obliteration of the Vermiform Appendix.—Dr. Biggs presented an appendix which had been removed from a man dying of chronic alcoholism. The appendix consisted of a small pouch about ¾ ctm. in length, and beyond this of a fibrous cord 2 mm. in diameter, which, apparently as a result of an old inflammation, had been united by adhesions to the neighboring tissues. The effect of this appendicitis had been to cause a complete obliteration of more than one-half of the appendix. Sections of the fibrous cord showed, under the microscope, unstriped muscular tissue, fibrous tissue, and many small round cells.

Sub-Diaphragmatic Abscess from Biliary Obstruction.—Dr. George Biggs also presented specimens from a patient, sixty-four years of age, who was admitted to the New York Hospital, March 19th, with a history of syphilis, alcoholism, and malaria. For eight years he had had attacks at intervals of from two weeks to two months, beginning with a sharp chill, and followed by fever and sweating, but without any pain or jaundice. The attacks were preceded by a more abundant flow of pale urine, and followed by a diminution in the secretion of urine, and a darkening of its color. For the last three or four years there had been deep jaundice. Five weeks before his admission he experienced for the first time considerable soreness to the right of the umbilicus, and eleven days before coming to the hospital he had one of these attacks, but this time it was associated with severe pain. On admission his pulse was 88; respiration, 24; temperature, 96° F.; in fact he was nearly moribund. The area of hepatic dulness was found to extend from the fifth rib to two inches below the free border of the ribs, and below this point the distended gall-bladder could be felt. He died rather suddenly of heart-failure.

At the autopsy the liver was found to be considerably enlarged, and for two and a half inches below the free border of the liver was the distended gall-bladder. The right thoracic cavity contained 1,000 c.c. of yellowish fluid containing biliary coloring matter. Just beneath the diaphragm was another collection of fluid, between the upper surface of the liver and the diaphragm, measuring 800 c.c. Below the diaphragm the wall of the cavity was formed by adhesions between the left lobe of the liver, stomach, duodenum, transverse colon, and the side of the gall-bladder. There was also a recent perforation through the centre of the right half of the diaphragm, connecting this cavity with the right pleural cavity. An abscess the size of a hen's egg, at the junction of the right and left lobes, communicated with the abscess on the left lobe of the liver, and with the fundus of the gall-bladder by an ulcerated opening 2 × 1 c.c. The cystic, hepatic, and common ducts were very much dilated. In the hepatic duct was a wedge-shaped block of cholesterine, two inches in its largest diameter, the small end projecting downward. The opening of the common bile-duct was perfectly normal. The fluid in the abscess cavities contained large numbers of minute black calculi. The large gall-stone probably formed in the gall-bladder and passed through the cystic into the common duct, and back into the hepatic; it probably caused obstruction of both the hepatic and cystic ducts. The rupture into the thoracic cavity certainly occurred only a short time before death.

Abscess of the Liver.—Dr. D. H. McAlpin presented specimens from three cases of abscess of the liver. In the first case there were multiple abscesses of the liver with perihepatitis, adhesions to the diaphragm, adherent pleura, rupture, and expectoration of muco-pus. Although there was no history of diarrhœa there were necrotic areas in the intestine, and the amœba of dysentery was found in the intestine. In the second case there was an abscess of the posterior superior portion of the liver which was enclosed by adhesions to the diaphragm. It pointed in the hypochondriac region, and the incision was made at this point and drainage established. The intestines were normal. In this case there was a history of a "strain" from lifting a heavy weight. The third patient was an Italian, with an ulcerating carcinoma of the pylorus. Sections under the microscope showed multiple abscess, and around the portal vein round-cell infiltration and beginning abscess formation.

Small Cirrhotic Kidneys—Acute Uræmia.—Dr. J. W. Brannan presented specimens from a man, forty-seven years of age, who had been taken ill on April 5th with cough and rapid respiration. There was no alcoholic history. On admission he was unable to talk although not comatose; pulse, 125, irregular and weak; respirations, 44; temperature, 98° F. There were a few râles over the lungs, and a diastolic murmur at the base of the heart. About fifteen hours before death the temperature was 98° F. in the rectum. At the autopsy the left lung was found adherent throughout; the pericardium was adherent to the heart; the heart was hypertrofied and weighed 16 ounces. There was atheroma of the aorta; the brain was normal except for some anæmia. The two kidneys weighed 3½ ounces, and the urine found in the bladder had a specific gravity of 1.009, and contained three-fourths per cent. albumin.

Intestinal Obstruction.—Dr. Brannan also presented specimens from a case of intestinal obstruction. The patient walked into the hospital yesterday morning complaining of pain in the abdomen. His temperature was 101° F. This morning at four o'clock he went to stool. One or two hours later he was found dead in bed. A hurried post-mortem examination made this evening showed nothing abnormal in the brain or lungs; the kidneys were large and firm, and showed the lesions of chronic diffuse nephritis; the heart was small and the left ventricle thickened. An examination of the abdominal cavity showed chronic peritonitis and some recent exudation of lymph. A portion of the transverse colon was constricted and congested, and its mucous membrane softened. Death probably resulted from this obstruction.

The Society then went into executive session.

To Supplement the Trained Nurse.—A new form of training has been undertaken by the Massachusetts Emergency and Hygienic Association—namely, the opening of a new occupation for young women who desire to become attendants upon chronic invalids, aged persons, convalescents, and sickly children. There are many families where it is inexpedient or impracticable for the relatively well members to wait upon those other members who may be feeble or sick. The trained nurse's attentions are a step above what is required in such cases, and are, perhaps, too high-priced for a long-continued service, as in the case of a confirmed invalid. It is at the time when the trained nurse takes her departure that the trained attendant may often do much good. And some discipline and instruction will make the latter fit to take up the work of the former.—*New York Medical Journal.*

OUR LONDON LETTER.

(From our Special Correspondent.)

FIBROID TUMOR OF BROAD LIGAMENT—CALCULUS WITH A BODKIN AS NUCLEUS—ANENCEPHALOUS MONSTERS—PLACENTA PRÆVIA—LONGINGS BY PREGNANT WOMEN—ABSORPTION OF UTERINE FIBROIDS—ABANDONMENT OF IRIDECTOMY—FIRES AND HOSPITALS—COLLEGE OF SURGEONS—OUT-PATIENTS WITH MENTAL DISORDERS—HARVEY TERCENTENARY—LAW-SUIT BETWEEN QUACKS.

LONDON, June 24, 1893.

At the last meeting of the Obstetrical Society (June 7th) Dr. Handfield Jones exhibited a fibroid tumor removed from the left broad ligament, and which has been associated with ascites, giving rise to a fear that it was malignant. At an exploratory operation about ten pints of fluid were removed, and the nature and attachment of the growth revealed. Dr. A. Routh related a case of calculus formed round a bodkin, which the patient, a women of forty-eight, admitted she had introduced twenty-one years before, and it had slipped from her fingers and was never seen afterward. He also showed an anencephalous monster. The skin was missing over the vault of the skull, and was replaced by a membrane, perhaps the dura mater; the parietal and frontal bones were wanting, and the basilar bone very rudimentary. The brain and cord seemed to be absent, but there were traces of an envelope. Dr. Bland Sutton said he had satisfied himself that in these cases a spinal cord did exist in the shape of a tube, with very delicate walls, from which the nerves arise. If the skull be floated in water in a fresh specimen, the sac could be clearly seen with brain matter within, and continuous with the tube in the spinal canal. Of course, if the membrane over the skull be ruptured during labor, the brain substance escapes and might be looked upon as fatty matter.

Dr. Pollock related a case of placenta prævia in which no hemorrhage had occurred before labor, unless what the woman called "bleeding piles" may be so considered.

Dr. A. Giles then read a paper on the "Longings of Pregnant Women." He had wished to determine whether these were due to disturbed nervous action, or were cravings for some material necessary to the mother or fœtus. He had inquired into three hundred cases of natural craving as distinguished from those clearly morbid. He found "longings" immensely more common in primiparæ than in multiparæ. They decreased with each child born. They were also much less common in the unmarried. The author of this laborious inquiry concludes that numerous cases are really only felt in consequence of the popular tradition on the subject. Perhaps the disturbance of digestion which is so common may give rise to fancies which at other times would be unnoticed, but, in the impressionable condition of nervous primiparæ familiar with the popular tradition, assumes unusual importance in the patient's mind.

Mr. A. Doran then related a case of absorption of fibroid tumors of the uterus before the menopause. The patient had been injured by a fall; inflammation had been thus set up, followed by resolution of the inflammatory products, and then by slow disappearance of the tumor. Such cases, associated with congestion, inflammation, or injury, have been recorded by Rigby, Prieger, Playfair, v. Mosetig, and Guéniot. Moreover, Mr. Doran has collected thirty-seven cases of the disappearance of fibroids—some not complete—and although errors of diagnosis may be suspected, so many cases by experienced authorities leave little doubt that such tumors do sometimes disappear spontaneously.

The abandonment of iridectomy is a subject interesting many just now. At the Ophthalmological Society (June 8th), Mr. Swanzy gave an account of one hundred operations for uncomplicated senile cataract by the combined method, the iridectomy as he performs it giving rise to very slight deformity. Mr. Critchett rather supported Mr. Swanzy, as did several others, but the President (Mr. Power) said, notwithstanding the carefully reasoned arguments, he preferred the simple operation, and thought the iridectomy added to the risk. A member asked whether anyone present, if he had only one eye, would deliberately select the simple operation? To this the president replied he would without hesitation. A show of hands was asked, and nineteen were in favor of the combined and four for the simple operation. Additional interest attaches to this discussion, as the next day the Bowman Lecture before the society was delivered by Mr. Pridgin Teale, who is known to have given up iridectomy, and took for his subject the question of its abandonment. He thinks the whole question hangs on the exact incision made, and he described in great detail the operation he performs, and the lessons he drew from his last one hundred cases. The incision he makes is entirely within the cornea, is almost linear, and yet without iridectomy. He has employed his method for the last twenty years, with most satisfactory results as to vision and comparative freedom from complications, as well as to perfection of scar, pupil, and anterior chamber, and he thinks that anyone adopting his plan in all its details would surpass his former successes either with the so-called simple or the Graefe operation with iridectomy.

The terrors of a fire are greatly increased when it occurs in or near a hospital. While I was writing my last week's letter there was an outbreak in premises next to the Royal Free Hospital. Happily, the wind was blowing in the direction away from the hospital. Otherwise, we should probably have had to lament a horrible catastrophe; as it was, some of the patients were moved to another part of the building, and preparations made to face the emergency. The hospital is provided with hydrants, and these were promptly brought out and did good service until the arrival of the fire brigade. This hospital is the one in connection with the Women's Medical School, and I am told that about thirty women students who were present at the time took their places at once, as they had been taught to do in a regularly held fire drill. I am also told that the surroundings of this hospital are a constant menace, not only from such stores of wood as were burnt this time, but on one side there is actually a cartridge factory. Surely some effort should be made to diminish these risks.

The approaching election at the Royal College of Surgeons is exciting interest even among those who have no vote. Sir William Savory at last definitely retires. He is credited with being the leader of the obstructives, and it is expected that the reform party will have a better chance.

St. Thomas's Hospital has started an out-patient department for mental cases, and is receiving the congratulations of medical journals on being the first to supply this want. And yet I remember how the journals, some years ago, scoffed at such a notion when an attempt was made to start a special hospital for the treatment of mental disorders as out-patients. Perhaps what was a scandal and foolishness, if not insanity, in a special dispensary, becomes propriety and wisdom when adopted by a big general hospital!

The tercentenary of Harvey's admission to Gonville and Caius College, Cambridge, was duly celebrated there on the 16th, when Sir J. Paget, Professor Huxley, and other London biologists and practitioners were present.

A curious trial took place this day week. A man whose name had been removed from the register sought to restrain a former clerk from continuing to publish a book alleged to be pirated from that of his *quondam* employer. It seems the clerk or assistant had set up as a rival quack, and it was alleged that he had also used, with alterations, testimonials addressed to his master as a curer of consumption. The judge thought the business might "possibly be a cruel and nefarious system of obtaining money by false pretences from persons who are induced

to believe themselves consumptive." He retained the books and papers in the custody of the court, and directed the official solicitor, and if necessary the public prosecutor, to look into the matter, with leave to either party, if so advised, to put the case into the paper for judgment on July 3d.

TO DETERMINE THE STOMACH END OF THE DIVIDED INTESTINE.

To the Editor of the Medical Record.

Sir: In your issue of June 24th you copy from the *Medical Press* a sodium-carbonate test for determining the stomachal end of the divided gut, regarding which I wish to mention an anatomical point that will meet every possible contingency in the matter under consideration.

Grasp the divided ends of the gut and hold them as though it was a simple, undivided loop of intestine, and so that the sides of the mesentery look to the right and left of the individual. Then place the finger in contact with the mesentery on one side, and gently pass it inward to the posterior attachment of the mesentery, keeping all the time in contact with the mesentery and using it as a guide. If the finger remains all the time on the side at which it was introduced, then up is up and down is down. If the finger starts in on one side and crosses to the opposite side of the abdomen and mesentery, then there is a half-twist in the loop, and what is held as the upper end is the rectal end of the loop or cut. If the finger leaves the side at which it was started, passing to the opposite side, and then returns to the side at which it was first introduced, there is a complete volvulus, and the direction of the twist and its extent is instantly determined. The anatomical basis of these facts is at once apparent when we remember that the mesenteric attachment of the small intestine is from the left of the median line above, downward, and to the right, ending in the right iliac fossa and crossing the spinal column. The test is instantly applied and gives vastly more information than that of any chemical test for determining the stomach end of a gut, and its accuracy is beyond question.

C. E. Ruth, M.D.

Keokuk, Ia.

HAIR-BALLS IN THE STOMACH OF THE OX.

To the Editor of the Medical Record.

Sir: Your issue of April 22, 1893, contains an account of an interesting case of foreign body in the stomach reported by Dr. Caroline S. Pease. This foreign body was found on autopsy to consist of the patient's own hair, strips of wool and cotton, shreds torn from a rubber protective sheet, and lacing cord from a camisole, the whole matted together and forming a solid mass weighing sixteen ounces. In this connection I deem it may be of interest to mention the "hair-balls" found in the stomachs of horned cattle, as their existence, I am satisfied, is unknown to most people. In the spring, when the long suit of winter hair is removed to make place for the new spring coat, the removal is chiefly accomplished by the process of licking the hair with the tongue. Most of the hair so removed adheres to the tongue, and is taken into the stomach with the food. If no great amount finds its way to the stomach at any one time, it is presumably passed on through the intestines and voided with the dung. If, however, it is swallowed in large quantity, it balls up and remains in the stomach. These balls become hard and dense, and attain considerable size. One on the desk before me has a circumference of twenty-six centimetres, is almost round in shape, and would make a good baseball if covered with leather, as it is so hard and firm. Smaller ones are sometimes passed *per vias naturales;* but large ones are usually found in the stomach when the animal is killed. They seem to give rise to no symptoms of discomfort, and never seem to produce ulcerations. Very truly yours,

James B. Bullitt, M.D.

Globe, A. T.

POST-PARTUM APPENDICITIS.

To the Editor of the Medical Record.

Sir: Dr. H. M. Neale, in the Medical Record for July 1, 1893, states that he has discovered several cases of post partum appendicitis, and he believes many of the cases of so-called post-partum cellulitis, pelvic abscess, ovaritis, and salpingitis, to be in reality appendicitis. This opinion is quite in line with my own observations in cases in which cœliotomy has given opportunity for verifying the diagnosis. Dr. Neale supposes that because labor contractions subject the abdominal contents to a high degree of pressure, cæcal contents are forced into the appendix, causing inflammation. This latter theory is not borne out by post-operative examination of specimens. Childbearing women and athletes frequently crush the adenoid layer of the appendix by subjecting the appendix to forcible compression against the pelvic wall. Symptoms of appendicitis may then appear almost immediately or after the lapse of weeks or months, the extent of the disturbance depending principally upon the amount of exudates in the tissues of the appendix, and the resulting opportunity for bacteria to make inroads and excursions. Prompt operation through the inch-and-a-half abdominal incision, by good surgeons, should give, in appendicitis, the death-rate of tooth-extraction, and will confine the patient to bed for a few days only, leaving an unimportant scar.

Robert T. Morris, M.D.

133 West Thirty-fourth Street, New York, July 1, 1893.

DRAFT OF A PROPOSED BILL TO ESTABLISH A BUREAU OF PUBLIC HEALTH.

The New York Academy of Medicine,
No. 19 West Forty-third Street, July 12, 1893.

The undersigned, a committee of the National Quarantine Committee of the New York Academy of Medicine, have been instructed to prepare a bill to be submitted to Congress, creating a Public Health organization in the General Government. With a view to harmonize conflicting views on the plan of organization, about which there is a diversity of opinions, in order to concentrate upon a single measure the efforts of all who are interested in securing the necessary legislation, we herewith tentatively submit the sections of a bill organizing a Bureau of Public Health, for the purpose of eliciting a full and free discussion of the subject before finally determining the precise form which the committee will adopt. While the committee believe that the plan submitted is more nearly in accordance with the opinions of those whose judgment and experience are most valuable, it is prepared to give due consideration to any modifications which may be proposed. The remaining features of the bill, which define the functions of the Bureau, will be submitted hereafter. All communications addressed to the Secretary of the Committee, Dr. J. H. Girdner, will be duly considered.

Joseph D. Bryant, *Chairman.*
Richard H. Derby.
Edward G. Janeway.
T. Gaillard Thomas.
David Webster.
Stephen Smith.
J. H. Girdner, *Secretary.*

A Bill to establish within the Treasury Department a Bureau of Public Health.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled:

Section 1. That for the purposes of this Act the States and Territories of the United States be and are hereby grouped into districts, to be known as "The Sanitary Districts of the United States," as follows:

The Northern Sanitary District shall include the States of Illinois, Indiana, Iowa, Michigan, Minnesota, Ohio, Wisconsin.

The Northeastern Sanitary District shall include the States of Connecticut, Massachusetts, Maine, New Hampshire, New York, Rhode Island, Vermont.

The Northwestern Sanitary District shall include the States of Idaho, Montana, North Dakota, Oregon, Washington, and the Territory of Alaska.

The Eastern Sanitary District shall include the States of Delaware, Maryland, New Jersey, Pennsylvania, Virginia, West Virginia, and the District of Columbia.

The Western Sanitary District shall include the States of California, Nevada, Utah, and the Territory of Arizona.

The Southern Sanitary District shall include the States of Arkansas, Alabama, Kentucky, Louisiana, Missouri, Mississippi, Tennessee.

The Southeastern Sanitary District shall include the States of Florida, Georgia, North Carolina, South Carolina.

The Southwestern Sanitary District shall include the State of Texas and the Territories of Indian Territory, New Mexico, Oklahoma.

The Central Sanitary District shall include the States of Colorado, Kansas, Nebraska, South Dakota, Wyoming.

Sec. 2. That there shall be established in the Treasury Department, under the direction and supervision of the Secretary thereof, a Bureau of Public Health, to consist of a Commission of fifteen, of whom eleven shall be appointed by the President, by and with the advice and consent of the Senate, as follows, viz.: One Medical Commissioner from each of the "Sanitary Districts of the United States," provided in section one of this Act, and two commissioners at large; the compensation of the appointed commissioners, when actually engaged in the performance of their duties under this Act, shall be ten dollars per diem and reasonable expenses. The other four members of the commission shall be the Surgeon-General of the Army, the Surgeon-General of the Navy, the Supervising Surgeon-General of the Marine Hospital Service, and an officer, learned in the law, detailed by the Attorney-General from the Department of Justice; these four members shall receive no compensation.

Sec. 3. That the members of the Commission shall meet at such time and place as may be designated by the Secretary of the Treasury, and organize by the election, from their own number, of a President who shall be one of the members at large, and who shall receive five dollars per diem, in addition to the ten dollars per diem provided in the last section, when actually engaged in the performance of his duties under this Act. The Commission may appoint a Secretary, not one of its number, and fix his salary at a sum not exceeding three thousand dollars annually. The Commission shall thereafter meet annually, at Washington, on the first Tuesday of October, and at such other times and places as the President of the Commission, with the approval of the Secretary of the Treasury, shall designate.

Sec. 4. That there shall be an Executive Committee of the Commission, consisting of its President, the Surgeon-General of the Army, the Surgeon-General of the Navy, and the Supervising Surgeon-General of the Marine Hospital Service and the officer detailed by the Attorney-General. The Commission shall from time to time prescribe the duties of the Executive Committee, and may make all needful rules and regulations for its own control and for the guidance and discipline of all its officers and employees, and shall establish all rules and regulations for the government of national sanitation in all of its foreign and interstate relations, and special departments in the enforcement of the provisions of this Act.

Sec. 5. That when, in the opinion of the President of the Commission the interests of the public health would be promoted by a conference of the Commission with the State Boards of Health of the Several States, or of any sanitary district or districts, he is hereby authorized to invite, with the approval of the Secretary of the Treasury, said State Boards of Health, or such number thereof as he may designate, each to delegate one of its members to meet the Commission in conference at such time and place as he may appoint; the President of the Commission shall be the President, and the Secretary of the Commission shall be the Secretary, of any such conference; the delegate in attendance upon the conference from each State Board of Health shall be entitled to receive reasonable compensation for expenses for a session not exceeding three days, to be paid on vouchers provided by the Secretary of the Treasury.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 8, 1893.

	Cases.	Deaths.
Typhus fever	3	0
Typhoid fever	11	4
Scarlet fever	81	15
Cerebro-spinal meningitis	9	20
Measles	173	16
Diphtheria	130	45
Small-pox	5	0
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Honors to a Physician and Journalist.—*The Lancet* says: "All that is most estimable in Parisian society assembled last Sunday in the Rue Lutèce to do honor to a great, though tardily appreciated, Frenchman — Théophraste Renaudot, founder of the Assistance Publique à Domicile, and—through his *Gazette* for procuring work for the unemployed—the father of journalistic enterprise in France. The commemorative movement which culminated in last Sunday's ceremony was initiated by Dr. Gilles de la Tourette, whose biography of Renaudot has assumed the place of a French classic, while the president of the committee organized *ad hoc* was the distinguished publicist, M. Jules Claretie. The monument itself—a life-like statue of the philanthropic physician in sitting posture in the act of giving ear to some poor applicant for work or medical assistance—is a *chef d'œuvre* of the sculptor Boucher, and on its being unveiled before the vast and brilliant assemblage, seemed, in the very suddenness of the process, to typify the new light that had dawned on the people of Paris, not only as to the merits, but as to the very existence of one of their greatest benefactors. The details of the monument, especially in the inscriptions engraved on the sides of the pedestal, tell the story of the man whose name and date of birth and death are all that are set forth on its front: "Théophraste Renaudot, 1586–1653." Dr. Gilles de la Tourette, in consideration of his exertions in preparing for the successful commemoration of Dr. Renaudot, has received from M. Dupuy, the French Premier, the insignia of the Legion of Honor.

Chicago's Ship Canal.—Dr. N. S. Davis, Jr., in a paper on "The Influence of the Ship Canal now being constructed by the Trustees of the Chicago Sanitary District on the Sanitary Conditions of Chicago and the State of Illinois," said that the canal would not decrease mortality one per cent. The sanitary condition of a city depends upon the thoroughness of soil drainage, proper disposal of sewage, purity, and abundance of water, and the habits of the population. The completion of the ship canal will in no way lower the level of the water in the river or the lake. Soil drainage will not be affected. It makes no difference whether the current moves toward the lake or toward Joliet, provided it moves to the same level. Chicago rests on a bed of blue clay impervious to water, covered with a thin layer of sand, in wards First, Second, Third, Fourth,

Twenty-first, Twenty-second, Twenty-fourth, Twenty-fifth, and Thirty-second, and not so covered in wards Fifth, Sixth, Seventh, Eighth, Ninth, Tenth, Fifteenth, Sixteenth, Seventeenth, Eighteenth, Nineteenth, Twentieth, Twenty-third, and Twenty-seventh. The mortality in the latter series of wards is thirty per cent. in excess of that in the former. The thin layer of sand admits of soil drainage, the blue clay does not. The new ship canal can in no way influence the two districts mentioned so long as the height of sewers over the surface of the water remains the same. The theory that running water purifies has been exploded by experiments in London and Paris.

A New Opening for Medical Men.—At cattle shows and other exhibits of live stock it goes without saying that experts in their respective departments must be retained for judging the animals, and in a somewhat similar manner, says the *Medical Press*, the service of a number of medical men were requisitioned for the purpose of judging the "quality" of the exhibits in a baby show which was recently organized in Melbourne. Everything progressed smoothly in this direction up to a certain point, but trouble began when it was found that nothing had been specified by the contracting parties respecting the remuneration which the judges were to receive. The management, it would appear, thought that the fact of being associated with the exhibition was a sufficient recompense for their medical judges; the latter, however, thought otherwise. The result has been a deadlock. The medical judges struck, and refused to give certain required certificates pending the payment of their fees, which, though not promised, were none the less expected. Of course, little hitches of this kind are to be expected in the inception of every movement and we see no ground for discouragement in this incident. The possibilities of the scheme are immense. The Pediatric Section of the coming Rome Congress might set aside a day for the discussion of "points" on babies, and for the establishment of an international standard of excellence. This would relieve the judges in future contests of any charge of partiality or unfairness which might be brought by disappointed and wrathful mothers. Then, with an inflexible fee-table, all difficulties would be removed and a new and lucrative specialty would have been successfully established.

Erroneous Ideas on Ptomaines.—Considerable misconception—not to say fundamental ignorance—is prevalent on the subject of ptomaines. This may clearly be seen from letters and articles which have appeared in the press since the recent sardine poisoning case, and also from statements made by medical men under conditions calculated to lend authority to their utterances. A case recently tried in a northern town and an inquest held only a few miles from the same town, have brought out assertions regarding ptomaines which are almost as erroneous as the announcement in a popular weekly review that "ptomaines are bacteria." As for obvious reasons the erroneous statements made in connection with this subject are extremely dangerous, since they may lure the public into a feeling of safety or comfortable responsibility, it is desirable to point out some of the commoner and, at the same time more dangerous, misconceptions in regard to these poisons. We hear it stated sometimes that all ptomaines are destroyed by such an amount of heat as is employed in the ordinary process of cooking. This might be so, if it were the case that ptomaines were bacteria, but if it were so, cases of food poisoning would be unheard of. Anyone acquainted with Brieger's work and the chemistry of these toxines knows how stable and resistant against heat almost all, and especially the more important, ptomaines are; and that, therefore, there can be no safety in boiling so far as the destruction of these bodies is concerned. Moreover, in the separation of many of these substances heat is constantly employed without the slightest effect on their toxic properties. Analogous observations are almost daily made during the preparation of the chemical products from pure cultures of bacteria, where heat is constantly used to destroy the micro-organisms. If there be death in the pot, generally speaking no amount of boiling will prevent it. Another statement which invites unqualified dissent is that by boiling the poison will be distilled out and so much diluted by the water used as to become innocuous. Most ptomaines —there are exceptions—are very soluble in water, but it is absurd to assume that if hidden in the centre of a piece of meat they would diffuse through the tissues and be dissolved and diluted. Lastly, the fact that of several people who have partaken of a tainted article of food only one has suffered has been used as an argument against the toxic nature of such food in any particular case. Can anything be more erroneous? The poison may be extremely localized in a particular piece of meat, the rest being free from it; and when we have to deal with a number of fish packed in the same tin, some only may be tainted, as was well shown in the case investigated by Dr. Stevenson, as here, moreover, the boiling oil in which the sardines are placed had not destroyed the lethal substance. The prevention of food poisoning is a problem of extreme difficulty. In the meantime, however, we must remain fully alive to all the results of accurate chemical and physiological observations and not lull ourselves into a feeeling of safety while we may be face to face with death, all the more deplorable as it is unforeseen, accidental, and fortunately rare.—*British Medical Journal.*

Fellows of the College of Physicians in England are debarred from suing in courts of law to recover fees for services rendered. But curiously enough, the Fellows of the College of Surgeons suffer from no such interference with their rights.

A Duel of Physicians.—Dr. Ward, a physician to the Mizon mission, and a certain Dr. Méry, had a duel not long ago, the results of which were more serious than those of most French duels, Dr. Ward having actually been wounded. The injury was not very grave, however, and both parties are now happy and their honor is all right.

To Get Rid of the Odor of Iodoform.—Dr. W. Washburn, of this city, writes *à propos* of a recent item on the deodorizing of iodoform: "In the *Medical Summary* for June, 1893, an article by myself gives an easier and more convenient method. It is there stated that both ether and chloroform are solvents of iodoform, and will remove every trace of it and its odor if the hands are washed with a trifle after washing with soap and water. The hands have a peculiarly clean feeling after using chloroform, dry instantly, and require no further washing. As nearly every physician carries ether or chloroform in his satchel, and as turpentine would be an additional burden, there is this also in favor of these drugs, they are always at hand. When clothing has been saturated with iodoform the proper thing is to first apply chloroform to the spot and rub it in, then wash with castile soap and water, and finally apply chloroform—or ether will do as well if chloroform is not at hand. Any seams coming within the space to be cleaned will require careful attention, just as the nails will if the hands are to be deodorized. The proper way for the nails is to dip a bit of soft wood (a match whittled flat is handy and efficient) in chloroform and with this clean under the nails. I have derived great comfort from applying this method in daily practice."

Cycling.—Dr. A. D. Rockwell says that cycling, like all other methods combining healthful exercise with pleasure, can be abused, but taking it all in all he regards the bicycle as a most beneficent invention. He has seen great benefit to mind and body come from its judicious use.

In the Good Old Time.—Willis P. King, the funny doctor of the Missouri Valley, says when he was a boy there were three things known by their odor, viz.: a billy goat, a skunk, and a doctor.

Prophylaxis and the Kitchen.—Medical science seems to be encroaching on culinary art, as the following advertisement in a leading daily shows: "Man Cook. In hotel or private family; also has made a soup preventive for all contagious diseases; can furnish best references. Chef, Waverley Place, basement." There ought to be a big demand for this soup during the summer.

Cancroin.—In one of my former letters I mentioned the experiments which Professor Adamkiewicz undertook to establish the pathology and rational treatment of cancer, and the opposition which his first fragmentary communications encountered. He has now put forth a complete survey of his four years' laborious researches in this direction, and the opportunity is now given of thoroughly testing his theories. As the subject is still one of the most obscure as well as the most important, his publication will certainly be received with interest by all. He starts from the consideration of cancer as an infectious tumor, and his investigations have led to the discovery of the compound he calls cancroin, which he describes as phenol-vinyl-citronate, and which appears to be a toxine or ptomaine. This body is now obtainable for therapeutic purposes from Merck, of Darmstadt, and seems from the histories published to have a useful influence on the disorder. Let us hope that time will confirm the correctness of the author's observations.—Berlin Correspondent *Occidental Medical Times.*

Vinca Minor for Diphtheria.—Some excitement was aroused a little while ago at Munich by the remarkable success achieved by an unprofessional lady doctor, the widow of a chemist, in the treatment of diphtheria. The daily papers were full of her praise, and even physicians are reported to have allowed that a great number of patients had really recovered by the use of her medicine. In consequence, the government had taken steps to purchase her nostrum, which she had kept a profound secret, but as she demanded no less than one hundred thousand marks for the communication an understanding had been delayed. Luckily a physician of the town, Dr. Krüche, managed to obtain a sample of the preparation, which on examination was found to consist of a decoction of a common herb, vinca minor, so that fortunately the public purse has been protected from an expenditure which would naturally have eventually proved a grand disappointment. Perhaps the homœopaths will make a trial with it, for their Pharmacopœia contains a tincture of the herb, with a notice to the effect of its having proved useful in sore throat and colds.—*Occidental Medical Times.*

The Status of Hysterectomy in New York.—At a meeting of the Post-Graduate Clinical Society, Dr. H. T. Hanks said concerning the subject of cancer of the uterus: "Cancer of the uterus is receiving much attention to day, and we have arrived at a time when the operation of hysterectomy can be performed for its relief, with a very small percentage of death resulting. There are a number of men in this city who are thoroughly skilled in this field of surgery; at this moment the names of at least ten men occur to me, members of the New York Academy of Medicine, who I believe can do a hysterectomy as well as Martin. It is a common operation. I saw Dr. Kelly, of Baltimore, do two hysterectomies and one hysterotomy in one day. Several of us have done this operation twice in a day. It is a great satisfaction to know that we are doing this work as well as it can be done in England, Germany, or France. Of course there are many men throughout the country who do the operation very poorly. They take a course at one of the post-graduate schools, see a few operations at Bellevue, Roosevelt, or the Woman's Hospital, and then go home and try their hand at it. I know how difficult I found my first vaginal hysterectomy, and how easy it seems now. I distinctly remember how hard it was for me to do my first supra-pubic hysterectomy. As our experience with these cases grows, the operation becomes easier. If the specialist sees these cases early enough, the operation can be safely done. Following vaginal hysterectomy, there should not be over two per cent. mortality, nor over four per cent. following the supra-pubic operation."

The Fruits of Sanitation.—Considerable improvement in the public health has followed the hygienic awakening of Italy, as seen in a report by Dr. Panizza, which has recently been issued by the government. While the general death-rate for the whole kingdom was 28 per mille in 1887, in 1888 it had fallen to 27.5, and in 1889 to 25.6. In spite of the ravages of influenza in the two following years, the death-rate only rose to 26.4 in 1890 and 27.2 in 1891. The statistics of infectious disease show a diminution in the five years 1887 to 1891 equal to 43.17 per cent. Taking particular diseases, we find that while small-pox caused 16,249 deaths in 1887, it claimed only 2,915 victims in 1891. For measles the corresponding figures were 19,545 deaths in 1891, as against 23,768 in 1887; for scarlet fever 7,254, against 14,631; for diphtheria 11,691, against 24,637: for typhoid fever 18,938, against 27,273; and for puerperal fever 1,642, against 2,504, being a total of 61,985 deaths from infectious diseases in 1891, against 109,062 in 1887. These gratifying results, which may be called the first fruits of the new sanitary law, may be accepted as of excellent augury for the future.

Doctors and to Spare.—It is stated in the *Times* that Paris attracts so many doctors that some go hungry. Complaints of the policy of centralization that concentrates in the capital all the powers of government and nearly all cultivation of the arts and sciences are constantly coming from the provinces. To this policy Paris owes its absolute supremacy over the rest of France, and to it is due the fact that in every political crisis the question is not, "What will France do?" but, "What will Paris do?" This, of course, is a most proud and comfortable position—for the Parisians—but, as in the case of other forms of glory, once in a while the discovery is made that certain disadvantages and hardships go along with it. Among the severest sufferers from the centralizing instinct, it seems, are the doctors. At the last annual meeting of the Association des Médecins de la Seine, which about corresponds to an American county medical society, it was reported that a constantly increasing number of doctors was each year forced to apply for aid from the treasury of the organization. This, naturally enough, was regarded as a lamentable, even humiliating, revelation, and the statistics which explain the increase of poverty among the medical profession of Paris have attracted much attention. It is doubtful, so attractive is life in the capital to a man of science, and so great are the rewards it offers a chosen few, whether the obvious lesson to be drawn from these figures will be applied to themselves by many ambitious provincials, but with the hope that they might have that effect the society has made them public. It seems that, while the Department of the Seine with which Paris is coextensive, contains not quite a tenth of the total proportion of France, its inhabitants have to support a sixth of all the doctors in the country; in other terms, there is one doctor to every 1,100 Parisians, and in this calculation no account is made either of the unregistered physicians, who, though banned by the law, are numerous, nor of 1,787 of those useful persons whom the French call *sage femmes*, many of whom exercise, especially among the poor, the duties of general practitioners. In 1891, France had 12,324 doctors, and Paris 2,419, or a fifth, showing that the situation, bad enough then, is growing worse. So, too, does the fact that from 1886 to 1891 the total number of doctors in France has increased by 324 and in Paris by 231; in other words, the Department of the Seine has absorbed three-fourths of the increase. Such being the circumstances, it is not difficult to see why many young and unknown doctors, and not a few who are old and no less unknown, should find the struggle for a livelihood too difficult to carry on without assistance from their more fortunate brothers.

INTERNAL MASSAGE IN DISEASES OF THE NOSE AND THROAT.[1]

By W. FREUDENTHAL, M.D.,

NEW YORK.

ATTENDING LARYNGOLOGIST TO THE GERMAN POLYKLINIK; VISITING LARYNGOLOGIST TO ST. MARK'S HOSPITAL AND THE MONTEFIORE HOME; INSTRUCTOR IN LARYNGOLOGY, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

The great triumphs which the galvano-cautery has accomplished in the last few years, due greatly to the reasonable price combined with the practicability of the galvano-caustic apparatus, have increased the practice of "burning of the nose" to a degree that could hardly be foreseen a few years ago. Owing to the number of cheap batteries in the market, scarcely a physician can be found in New York who does not use this means with more or less judgment, often burning away all and anything that it is possible to cauterize. Whether or not this is detrimental to the patient will not be considered to-night. Nevertheless, experienced laryngologists frequently resort to the galvano-caustic point as the best means for removing certain anomalies, especially of a hypertrophic nature, in a quick and effective manner. But in the last few years it has been noticed that through repeated cauterization a cicatricial condition of the mucous membrane occurs, which often impedes its physiological function. However, as the galvano-cautery is the least injurious of all astringents, we have hitherto been obliged to accept it as the last resort.

For other conditions not hypertrophic in nature, the spray, with all its complicated modifications, has been used with preference more often here in the United States than in Germany and elsewhere. Although happy results in some exceptional cases are undeniable, as a whole it must be admitted that deleterious consequences must follow the use of so-called astringent and tonic sprays upon the delicate mucous membrane of the nose, especially when repeatedly used for a long time. Is it not well known how susceptible to irritation the mucous membrane of the nose is? And further, it is known that even distilled water injected into the nose causes irritation. The physiological salt solution alone, when it has the temperature equal to that of the interior of the nose, is harmless.

A treatment to do away, to a large extent, with the galvano-cautery and entirely substitute the spray, has been anxiously awaited by many laryngologists. This treatment has been found. It is the direct massage of the mucous membrane.

Michael Braun,[2] of Triest, was the first who tried to interest a larger circle in this treatment at the Berlin Congress. Soon afterward I began experimenting with it; but I was induced to work systematically in this field by the enthusiastic monograph of Laker.[3] And though at times, while reading his book, I felt that the author painted this new treatment in too brilliant colors, still I could not help thinking that, in spite of the severest criticisms, there was sufficient good remaining to warrant a trial of this therapy. Personally I should like to state that I have no reason to regret my own experiments in this direction.

Before we consider the application of this treatment we must ask, What is the physiological effect of massage? The principal office it fulfils is to regulate the local circulation of the blood. Through the experiments of Kronecker and Stirling it has been proved that massage acts by thoroughly perfusing and filtrating the tissues, which not only furnishes new building material, but removes very quickly the asphyctic and obsolete secretions. This latter statement is explained by the fact that massage affects the lymph circulation also, because not only the flow of the lymph, but also the reflux of venous blood, is accelerated. So massage indirectly affects the resorption both of normal and pathological fluids.

Massage, therefore, is indicated in cases where it is desirable to stimulate the normal physiological functions of the organism to produce a lively oxidation in the tissues, and to remove hyperæmias and inflammations. Furthermore, it is the best method of promoting resorption of all those pathological products which can be returned to the circulation without detriment to the organism (Alb. Reibmayr).

On the basis of these theoretical deductions, and the results obtained by others, I concluded to begin practical work in massage, but at once an obstacle presented itself—the method of applying this new treatment. Michael Braun's way of applying internal massage is as follows: He takes a copper probe, twenty-one centimetres long, as one holds the pen, in the right hand, bending the end according to the part to be treated, and covers the button-end with cotton, which he dips in a twenty per cent. solution of cocaine, in a ten per cent. menthol-vaseline ointment, in a ten per cent. iodide of potassium glycerine, or in sublimate, lanoline, vaseline, or Peruvian balsam. The field of operation is then illuminated, and the mucous membrane rapidly percussed by the vibrating probe. These vibrations are caused by movements of the operator's arm, emanating from his elbow-joint, his wrist being kept stiff and immovable. The probe makes gentle taps in rapid succession, about four hundred to the minute. Braun combines these with the "effleurage," manipulating not alone one spot, but, slowly stroking from this point, he covers the entire field of operation. The probes, naturally, are bent to a different shape for the naso-pharynx, pharynx, and larynx.

While Braun seats himself before his patient, Laker prefers to stand. The latter does not use illumination to carry out, as he calls it, the internal massage of the mucous membrane. His method is as follows: The thumb of the left hand upholds the tip of the patient's nose, while the four other fingers of that hand steady the head. The right hand holds the probe for vibrating, just as Braun advises. The head of the patient rests on a movable head-rest, attached to the operating-chair. Laker believes that after minute examination of the topography of the various internal parts of the nose, and by continuous practice, you gradually gain such a delicacy of touch that you could find your way in the dark with ease.

From a theoretical point of view this working in the dark did not seem to me to be worthy of imitation, and therefore I never tried it.

I. Herzfeld[1] experienced good results in cases of pharyngeal catarrh by brushing the throat with a great

[1] Read before the Section in Laryngology and Rhinology of the New York Academy of Medicine, May 24, 1893.

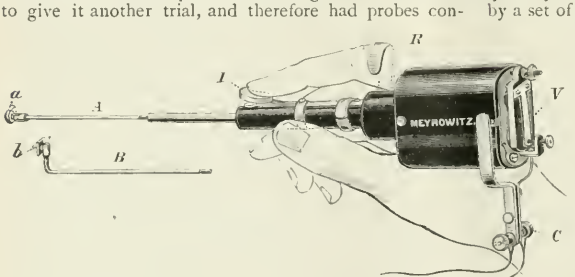
[3] Dr. Carl Laker: DieHeil-Erfolge der inneren Schleimhautmassage. Graz, 1892.

[1] Deutsch. Massage bei Hals- und Nasenkrankheiten, Die Med. Ztg. p. 999, 1890.

variety of drugs, and believed that the mechanical irritation was the effective agent alone, the brushing acting as a massage. A colleague, tells me the late Dr. Elsberg expressed a like opinion, inasmuch as he gave directions to rub the medicine thoroughly into the affected part. Herzfeld had instruments constructed worked by the so-called American dental drill. As these instruments only make rotatory movements, the parts are kneaded instead of vibrated. The instrument is also impractical in form for the nose, as it has the curved shape of all our other laryngeal instruments. H. Lahmann[1] also invented a new instrument for the same purpose, the probe-like end of which instrument is put in motion by a spring. For many reasons it is not useful. I do not know whether these instruments are much used, but I must add that Garnault,[2] whose article up to date is the latest on this theme, speaks of them. Garnault believes that the hand alone should direct the probe, and all other devices should be rejected. But he connects his probe with the electric current, thus applying electricity and massage at one and the same time, a method which many might take exception to. I have not tried it, being opposed to it on theoretical grounds.

In regard to the accomplishment of vibrating with the hand, it is extremely difficult, speaking from my own experience. Gentlemen, try to make three hundred to four hundred vibrations in a minute, and you will soon discover what a task it is to control the intensity and equalize the intervals. How much more difficult it is to increase the vibrations to one to two thousand a minute in like manner! Laker warns one not to be discouraged at lack of success at first efforts, and encourages by the promise of success after a few months of daily practice. How difficult the acquirement, and then how dependent the final result rests upon the exact fulfilment. Garnault gives a correct description, saying: "Il est absolument nécessaire que les vibrations soient extrêmement rapides, qu'elles soient régulières et de même intensité. Ces trois conditions indispensables sont en même temps inséparables. S'il n'en était pas ainsi, on déchirerait la muqueuse, et l'on augmenterait l'inflammation, que l'on prétend calmer."

Therefore, without exact vibration more harm is done than good, and to carry it out correctly means months of daily practice. These are disadvantages to be carefully considered. And these are the causes which led me, notwithstanding all objections made beforehand, to utilize electricity in preference to the muscular action of the arm as a motive power for massage. But I wanted to give it another trial, and therefore had probes constructed after the description of Braun and Laker, but I made very slow progress. Feeling uncertain whether my copy of the probe was exact, I sent to Dr. Laker asking him to forward me a complete set of his probes, and he kindly acquiesced. But my proficiency in the use of these new probes being very slow, I again returned to my original idea, namely, of using electricity as a motive power. I will not tire you with the long, wearisome process, and the numerous discouragements I had to contend with. You all know the difficulties encountered in having a new instrument made. One point, however, deserves mentioning. I had determined from the start not to use the dental drill, as this appliance has for years been eliminated from our laryngological armamentarium. Dr. Boedecker, a dentist of this city, drew my attention to an appliance now greatly used in dentistry, known as Webb's electric mallet. It drives the filling firmly into the cavity of the tooth. To accomplish this, the anterior portion of the instrument is stationary, while the rear end makes the strokes. As elegant and finished as this apparatus is, it would not answer our purpose, as it does not give a direct concussion of the mucous membrane, but one of indirect contact. Naturally, the form of the anterior portion had to be changed for our work. And now I went to work to construct a hammer driven by electro-magnetism, whose strokes would be direct. I gave detailed instructions to a number of instrument-makers; some could not and others would not attempt it. Mr. Charles Spiro, a lawyer and friend of mine, in his leisure hours made a model, for which I am indebted to him. Then E. B. Meyrowitz, of this city, after several attempts, made the electric vibrator, in its completeness, after this model, as you now see it. The mechanism is, in short, as follows: Two magnets occupy the interior of the box. Around these magnets coiled wire runs in manifold windings. Between these two magnets a rod is placed, destined to move backward and forward; at its rear end an iron plate is fastened, and to this is attached a movable metal plate. To the front end of the rod is screwed a detachable part, which I call the probe, *A*, the button of which, *a*, is movable. The index-finger slips into a holder, *R*, which is attached to the neck of the instrument, the box resting between the thumb and the index-finger of the operator. Two little screws at the lower part of the box are points of attachment for the electric wires. On the neck is placed a metal spring, which holds the ivory button *I*. When this is pressed upon by the tip of the index-finger, the current is closed and the iron plate is drawn forward by the magnet, which at the same moment has become electro-magnetic, and, as a matter of course, the rod holding the probe is drawn forward also. As soon as the iron plate has reached its foremost point, the contact is interrupted directly before the screw, and the iron plate falls in its original place, driven by spring power. The next instant the current closes again, and the mechanism repeats itself over and over. The quantity and quality of the vibrations can be regulated by a set of screws attached to the rear of the box. I had the tone produced by the oscillations of my instrument tested by a learned musician, to find out the number of vibrations it makes to the minute. Mr. Sam Franko asserts that the tone corresponds to the deep *C* and to the deepest tone of the viola, making 132 oscillations to the second, or 7,920 to the minute, which is considerably more than is possible to produce with the hand.



To use this instrument neither practice nor dexterity is necessary. Any person accustomed to use instruments can operate it at the first trial.

I generally illuminate the parts I am vibrating, and agree with M. Braun, inasmuch as I combine massage with effleurage. To vibrate the nose, I dilate the nostrils with a speculum and use probe *A*. When I intend to treat the septum, or parts lying sidewards, I turn the button *a* toward the right or the left. But if the patient is directed to turn his head to one side instead, this is often unnecessary. To massage the oro-pharynx I also use probe *A*, with straightened end. For the retropharynx I apply probe *B*, placing its buttoned end (*b*) either straight or upward, as shown in the Figure. When I place the probe not at right angles to the part to be massaged, but at an acute angle, or parallel to it, the instrument does not tap, but rubs the part.

[1] Die innere Nasenmassage, Allgem. Med. Central Ztg., 1892, p. 774.

[2] Le Massage vibratoire et électrique des muqueuses du nez, du pharynx et du larynx, La Semaine medicale, 1892, p. 354.

I vibrate from ten seconds upward. At the beginning, when the patients are not accustomed to the treatment, I do not use the probe longer than about five seconds, lengthening this time each visit. I endeavor to manipulate the entire surface of the nose or throat, or both, commencing with the pharynx, moving slowly downward and upward the posterior wall of it, then from side to side. Then the retropharynx is treated in like manner. I then touch in the nose those parts directly in front of me, *i.e.*, often hypertrophies of the middle and lower turbinated body, then come the parts lying sideways, *i.e.*, the septum, alæ nasi, and the other turbinated bodies. To oppose all suggestions that the drugs used in connection with vibration were the effective agents, I have from the start applied massage preceded by an application of cocaine only. A five per cent. solution was generally sufficient; in but a few instances I resorted to a ten per cent. solution. This is applied, before I massage, with a small bit of cotton. While lesions might occur and bleeding take place more easily by my instrument than by the ordinary probe worked by the hand, yet all this can be prevented by illuminating the parts and carefully moving the probe from spot to spot. If attention is paid to these details, it will be unnecessary to cover the buttoned probe end of the instrument with cotton, and bleeding will be less frequent than from an ordinary probe. Each time before I use the probe I wash it with hot water, and after using it I lay it in a ten per cent. carbolic acid solution, or when boiling water is convenient, I prefer that. Stronger disinfection I consider unnecessary, for the simple reason that we do not thoroughly disinfect other instruments, as, for instance, the laryngeal mirror, without risking infection. However, it is advisable, in cases having a specific origin, to have a separate probe.

As motor power I use Ford's storage battery, three cells of which are sufficient to drive the apparatus.

After overcoming the chief obstacle by constructing an electric vibrator, I could more easily commence work, and now comes the question: What results can we obtain by such vibration? After an experience of almost two years, I at once declare that I am not as optimistic as Laker and others, yet at the same time I cannot condemn the whole matter, as does Chiari, who regards it as child's play. It is but natural that such enthusiasm as Braun and Laker felt over the success of this newly found method could not be permanent, but so much good remains that, for the present, we are forced to give it our earnest attention. And when Chiari states that he neither cured nor improved a single case by vibration, it is a peculiar coincidence, to say the least. But he had to bear Laker's reproach when he was told that a patient, after unsuccessful treatment by many eminent specialists, and among these Chiari himself, was entirely cured by Laker with no other remedy than vibrating massage. The patient was a physician. And when Chiari replied that he had met with success by certain treatments when all other methods had failed, he involuntarily concedes massage to be a proper method of treatment. That this one cure of Laker was not exceptional will be proven later by the citation of a number of others.

And now we will consider some of the diseases which I have treated. To begin with acute diseases, I have treated experimentally ten cases of acute coryza. Not alone was the bleeding somewhat stronger than usual, but the result was such as not to promise an improvement over the old method. Such acute troubles are cured by every possible method, and in none of these cases can I positively say the attack was shortened. And when Cramer,[1] in an experience of two cases, speaks in favor of massage in acute catarrh, I should imagine that his remarks are rather premature. Follicular angina and diphtheria I have not treated with massage, as I coincide with Reibmayr (*loc. cit.*), who says: "It is contraindicated in all parasitic and infectious diseases; furthermore, in all inflammations and diseases where the inflammatory product has developed a quality pernicious to the organism."

[1] Deutsche Med. Woch., No. 22, 1890.

One of the most frequent diseases in the field of chronic troubles is chronic hypertrophic rhinitis. Here we find a number of cases which can be successfully treated by massage, I am almost tempted to say, must be. Take the following case as an example:

Miss B. S—— came to me after being treated for four years by many physicians for "catarrh and speaking through the nose." She has a diffuse rhinitis, both nostrils narrow, especially on the left side, where there is a slight deviation of the septum, the lower turbinated bone pressing closely upon it, although not much hypertrophied. It is remarkable that she was not galvano-cauterized, and probably for the reason that she had great fear of it; otherwise the common remedies, especially the spray, were frequently applied, but always with temporary relief only. And what could have been gained by galvano-cautery? Very little. The mucous membrane would have been partially destroyed on one spot without improving the others. And that sprays, powders, and local applications were of no avail, but each time provoked a new irritation in the affected mucous membranes, the young lady experienced to her own sorrow. In this case we required a fundamental change of the whole mucous membrane in all its layers, a regulation of the blood circulation, and a normal function, especially of the turbinated bones, and all this was most wonderfully accomplished by vibrating massage. After the sixth sitting both nostrils were free. But soon after she caught a cold and all the symptoms returned. After ten more sittings the whole mucous membrane looked normal, and has remained so up to the present, *i.e.*, for six months. The left lower turbinated bone does not touch the septum any longer, she speaks distinctly, and her eyes do not water as formerly. Besides, she is not so subject to cold, and when she has one she still breathes freely. I must again emphatically repeat that I used no drug, but massage only. The patient was and is teaching, and for the last eight months has been over-exerting herself preparing her class for an examination.

As a type of another series of cases I cite the following:

Miss Ida W——, aged thirty-two, was sent to me for an obstinate cough, oppression in the chest, difficulty in breathing, etc. After being treated by a number of physicians she grew so melancholy that her brother told me he feared to leave her alone. She considered herself incurable. She has a very broad nose, with an exceptionally straight septum. The turbinated bones are very much hypertrophied, so that the middle ones rest against the septum, while the lower ones almost touch it. Nasal breathing is impossible. In the pharynx there are catarrhal ulcerations on both palatine arches and a general hyperæmia. The lungs are free. The cough was stopped within a week by local applications of astringents to the pharynx, and mild internal remedies. On account of the large hypertrophies in the nose I did not consider this case appropriate for massage, nevertheless I gave it a trial, being determined to give it up shortly if the results were not favorable. After the eighth sitting I noticed the turbinated bones had decreased in size, the patient breathed easier, and felt, since the cough had also subsided, altogether better and in a happier frame of mind. After the twenty-third sitting the nose was, and has since, for four months, remained a perfectly free air-passage. Her turbinated bones are still large, but not larger than is natural in a large and broad nose. The pharynx had to be treated for a longer time, but in the end all subjective and objective symptoms disappeared.

As convincing as this case may appear, some one may not give all credit to the massage treatment, as one may ascribe the swelling of the turbinated bodies to the stagnation of blood caused by the cough. Be it as it may, it teaches one lesson worth learning: not to use the galvano-cautery too readily. For what would have been the consequences had it been used instead of massage?

After the acute state had subsided one would see enlarged turbinated bones, which prevented breathing. Naturally one at once would have cauterized, and again cauterized after the disappearance of a reactionary inflammation, and again and again, till a so-called normal condition was reached. But how often cauterized mucous membranes are rendered incapable of performing their normal function we all know. Therefore after such treatment an organ consisting largely of cicatricial tissue cannot perform its original physiological service, and this case cited would have added one to that number. Instead of that, however, it clearly shows that massage can reduce without disabling an organ so vital as the turbinated bodies, leaving normal conditions for respiration. Yes, more normal than ever before.

This massage treatment is still more feasible when we attempt to treat the entire mucous membrane, whether hyperæmic or generally slightly hypertrophied, than in treating selected affected areas. You are all familiar with such obstinate cases which occupy our attention without any perceptible improvement from treatment, and it is just for this class of cases that I draw your especial attention for internal massage. It accomplishes frequently what no other method can.

The following serves as an illustration:

Miss A. S——, aged nineteen, and very anæmic, was sent to me by her family physician on account of a very obstinate nasal catarrh, which he could not get rid of. The girl had constant colds in the head. The entire mucous membrane was always reddened and somewhat swollen, some secretion being always present. She has been vibrated twelve times, and has been perfectly well for the last three months. As a matter of routine, I vibrated her nose afterward fifteen to eighteen times more, but only to preserve the good results obtained. I see the patient monthly, and know that she is well. In such like cases I have always taken pains to manipulate the whole mucous membrane of the nasal interior, and the results were excellent. That, however, in these forms of catarrh, relapses occur, especially in the beginning of the treatment, I do not wish to deny, and in many a case I had to begin anew after I had reason to believe I had obtained a final result. But this must not mislead one, for if we have had a case so favorably influenced by internal massage we can be assured it will control a relapse in the shortest time.

As types of two other diseases I mention the following two cases:

John L——, a lad, thirteen years of age, born in England, has been treated by three well-known laryngologists in London on account of formation of crusts in the nose. These were usually lying in the right nostril, especially on the ala nasi; on the left side no crusts were to be found. There were no adenoid vegetations present, nor was there an outspoken atrophy of the nasal mucous membrane. The latter was rather in an acute inflammatory condition whenever I saw it. I treated the boy for eight months without a sign of improvement, when I decided to use the massage. After the fifth sitting a slight improvement was already noticeable; after the eleventh sitting no crusts could be seen on the right side, but for the first time quite a good many were to be seen on the left side. Therefore I applied internal massage on both sides. Once a hemorrhage occurred an hour after massaging. This, however, was the only time it occurred, as bleeding generally sets in during the manipulation, if it occurs at all. The boy had frequent relapses, and could be considered cured only after the forty-sixth sitting.

The second case is a Bohemian cigarmaker, with erythema fugax of the nose. Each time we have damp weather his nose is stopped up and the whole right side becomes red and swollen, giving a very ugly appearance and making him a butt of ridicule for his comrades. As dry weather begins all these symptoms disappear. An examination of the nose between the attacks reveals a slightly hypertrophied middle turbinated body on the right side, everything else looking normal externally and internally. It was only after the fourteenth sitting of massage that the symptoms began to disappear, the outer walls not growing red during an attack. After the twentieth sitting the anterior parts of the introitus narium also remained normal. I am convinced that nothing would have been gained in this case by astringents and tonics, as we could have only reduced the size of the middle turbinated body, and this would not have influenced the disease. I could infer this from the fact that after the middle turbinated body became normal in appearance the disease did not as yet cease. It required a fundamental stimulation of the whole mucous membrane to its deepest layers before a cure could be obtained.

However, that we cannot do without the galvano-cautery as some may infer, is evident. When we have a case of polypi, or where there are polypoid hypertrophies attached by a small pedicle to the mucous membrane, where it is probable that the main mass of the mucous membrane is left intact after cauterization, and only a very small portion of cicatricial tissue remains, in such cases we use the expedient galvano-cautery. Where, however, it is to be expected that we shall leave extensive scars through galvano cautery, put it aside and replace it by the slow, but surer, method of internal massage. The correctness of this statement I could verify by manifold proofs. An excellent one is a case treated by a well known laryngologist of Stuttgart, twelve years ago. The patient, now twenty-nine years of age, was sent to me for several throat troubles. His pharynx was marked in many places by numerous extensive scars, covering almost a half of the oro-pharynx. Between these scars lay masses of granulations, some projecting very strongly. The patient had been cauterized in a rational manner for granulations twelve years ago, and since then this was repeated by five different physicians here and in Europe. What would have been his condition had I, through cauterizing or scraping, changed the small remaining part of his mucous membrane into cicatricial tissue? The man's pharynx would have become a useless functioning organ for the rest of his life. My plan was different in that I chose the slower, and in this case a very tedious, method, massage. Subjective improvement followed the fourth sitting, but, objectively, it was not pronounced before the twenty-third and remained permanent after the thirty-sixth sitting. The proceedings which made the granulations disappear were so similar to those of chronic hypertrophic rhinitis that I will not repeat them. But the condition of the other parts of the pharynx in this case, namely, the atrophies, we will discuss at the same time as we do those occurring in the nose and pharynx, for the reason that the changes are similar. It will appear strange that I favor massage for atrophies, after having praised it for some forms of hypertrophic conditions. Chiari says: "The promoters of this new method, on one hand, claim that hypertrophies are decreased, and on the other hand, that the atrophic turbinated bodies are enlarged by the same treatment, just as if the mucous membranes were made to know how to answer satisfactorily to the demands of the vibrator." I allow myself one retort: Try it yourselves, and experience will teach you that nature does appear to understand how to regulate herself. More than once I have seen atrophic turbinated bodies enlarge after a short course of treatment. They grew larger and larger, and in one case, a girl of sixteen, I purposely stimulated the atrophic turbinated bodies to such a growth that, finally, they touched the septum on both sides. (I never repeated this experiment.) I explain this apparent contradiction thus: Massage, by causing a lively oxidation, not only creates a quicker supply of nourishing material to the part, but also a more rapid excretion of products from the part. This also explains the apparently contradictory cure of hypertrophies and atrophies. Through massage the tissue-fluids are driven mechanically into centripetal roads and forced to quicker resorption. That we do not in this instance have to deal with pure fluids, but cell elements and other substances are associated, which through massage are crushed and ground and then can

penetrate as detritus into the open channel, as Dr. v. Mosengeil had observed years ago. In this way it is comprehensible how hypertrophies can be removed. On the other hand, there circulates in the veins and lymph-vessels, during and shortly after massage, a greater quantity of their contents; secondarily, a large flow from the arteries must naturally follow, and more nourishment is then brought to these particular spots. This explains the cure of atrophic conditions. I treated a case which showed clinically the most outspoken picture of pharyngitis sicca. The patient had been suffering for fifteen years from dryness in the throat. I treated her with internal massage for eight weeks, with slight interruptions, without improvement; although she felt better right after each treatment the dry sensation very soon returned. Finally, in the ninth week, slightly reddened spots appeared on the sides, and at once she declared she felt much better. I treated the patient three months more, and finally was able to effect a perfect cure. This case was as clear a proof of the value of our new method as any case can be. The same improvement I could notice in the gentleman formerly treated in Stuttgart. The shining cicatricial places, so numerous in his pharynx, became, during vibrating, hyperæmic, a condition which disappeared naturally soon after. Gradually, however, a certain amount of these hyperæmias remained permanent, so that at last in place of these broad scars only narrow lines were left. As the granulations by this time had also disappeared from his throat, the patient, who by the way never had a specific disease, felt perfectly well.

Now, in which particular manner an atrophic mucous membrane which, according to all our pathological and therapeutical experience, is no more able to perform its function, can be brought back to its normal state, and especially what microscopical changes occur, I do not know. I know only so much, that before treatment I had such a very pronounced atrophic pharyngitis in the above mentioned case that you would expect to find absolutely no glands in the mucous membrane left, and afterward, a mucous membrane not only normal in appearance, but also secreting mucus was the result of the treatment. To the sceptics I should like to make known a word of Dr. Leopold Ewer, who in a recently published article says: "Practice goes over all theory. Look at a case of atrophic mucous membrane, look at it after often not too long a treatment, how it performs its function, and every doubt will be removed." The *Journal of Laryngology* (Editorial, June, 1892), says in this regard: "But the massage treatment of atrophic catarrhs would seem to hold out more favorable hopes than any other form of therapeutics, and this, indeed, is only what we should expect when we consider that such treatment must of necessity tend to restore the physiological integrity of a mucous membrane which has undergone trophic changes."

In the last year I have seen so few cases of ozæna that I have not attempted to use massage in this troublesome disorder. But I should like to mention that Demme has treated, at Professor B. Fränkel's clinic, sixty-four such cases with vibrations. Ten of these he considered cured in a most perfect manner, while among the remaining each and every one was improved.

We come now to the neuroses in the nose, and among these I mention only hay-fever. During the last season I had occasion to treat six patients with it; one lady before the attack and the rest during the same. The first came only eight times for treatment, and in August she had her attack, although not as strong as usual. Of the other five patients, whom I saw during their attack once to twice daily, the duration, without exception, was reduced from fourteen to ten days, while it formerly lasted four to six weeks and sometimes still longer. As an example is the following case: Mrs. M——, a nurse, forty years of age, born in Germany, but for nineteen years a resident in this country. For the last five years she has been subject to hay asthma. Last year it began on August 31st, in such a severe form as never before. At nighttime the water runs from her nose in such quantity that she is unable to sleep. On September 6th, I saw her for the first time and applied massage. During and right after this the discharge from the nose was simply enormous. The eyes also watered extremely. After two hours, however, both ceased somewhat. On the 7th, a second massaging, repeated in the evening. On the 9th, for the first time, she felt better. I treated her on the 9th, 10th, 12th, 14th, 16th, 18th, and 21st, at the end of which she was entirely free from her symptoms.

I have determined this year to treat the patients before the attacks, and to see whether it is not possible to check these entirely.

To come to the end, I have treated altogether a few hundred cases of different diseases with internal massage, but I do not consider it opportune to give you a statistical table of my success and failures. Figures are, if in any place, in therapeutics open to correction. But so much is evident from my experiments, and that you can see from the cases cited, that often in the most obstinate cases we get remarkable success, which must spur us on to further work in this field. Till now I have not used any other drug to massage in these cases, for the simple reason that this has been experimental work. And desiring my experiments to be clear, and without doubt of the efficiency of massage or its superiority to other methods, I had to use it alone without any associating drugs. Now, after having passed the stage of experimenting I shall not hesitate to combine in certain cases massage with other remedies, to see whether we cannot effect a quicker cure.

With the exception of the hay-fever cases, I have seen my patients not more than three times a week, some few four times, and quite a number only twice weekly. I have endeavored to judge of this new method as objectively as possible, and tried to show you its good and reverse sides, and after all this, I have come to the conclusion that internal massage is a remedy which will never again disappear from our therapeutic armament.

1054 Lexington Avenue.

CONCERNING THE SIGNIFICANCE OF PHAGOCYTOSIS.

By JOHN C. HEMMETER, M.D., Ph.D.,
BALTIMORE, MD.

My object in the following abstract concerning phagocytosis is to present some recent interpretations of the last part of the theory of Metschnikoff to which the latter still clings, namely, that the destruction of bacteria by leucocytes forms part of the general process of destruction of bacteria in the tissues of animals refractory to certain diseases, and that the destruction of micro-organisms in living tissues is accomplished by the cells of the body and by the cells only.

In 1886 Pfeiffer[1] first proved by systematic experiments, that certain chemical substances attract bacteria, and others repel them, and Baumgarten[2] explained the facts observed by Pfeiffer as having an important bearing on the movements of both cells and microbes within the infected human and animal body. The method of Pfeiffer consisted in placing the chemicals to be experimented on in tiny, very thin glass tubes, sealed at one end, which were submerged in fluids containing the organisms. The latter enter the tubes, if the substances have an attraction for them. For this phenomenon of attraction Pfeiffer invented the name *chemotaxis*. In case organisms were attracted to a substance he gave it the name *positive* chemotaxis; in case they were repelled, *negative* chemotaxis. Some substances which neither attracted nor repelled he called *indifferent* substances.

It is not clearly stated how indifferent substances are to be distinguished from substances of repelling chemotaxis. In both the tubes were free from bacteria.

[2] Jahresbericht, iv., 2, p. 358.

It is necessary to refer also to the experiments of Hess.[1] Hess studied the fate of anthrax bacilli injected into the circulation of the frog. Frogs are immune to anthrax, Metschnikoff and his school held that "the bacilli are taken up by the leucocytes of the frog, and there undergo gradual destruction. After huge quantities of anthrax bacilli had been injected into the circulation of the frog, Hess found that very few could be discovered in the blood after three hours and after six hours none at all. On placing a small quantity of a culture of virulent anthrax bacilli, contained between Ziegler's plates, into the tissues of one of the most susceptible animals to anthrax, the rabbit, comparatively very few leucocytes entered the culture. In case an attenuated form of anthrax culture was used in place of the virulent, leucocytes in large quantities entered the space between the plates and surrounded the organisms. It is important to bear these observations of Hess and others in mind, namely, that in case virulent cultures were introduced, few leucocytes entered the space between Ziegler's plates, whereas, when attenuated cultures of anthrax bacilli were used, to which the rabbit is immune, the leucocytes entered the space in large numbers. This observation corresponds to that of Tchistovitch.[2] He found that when rabbits were inoculated with attenuated cultures of the diplococcus Pasteuri in every case there was an increase in the number of leucocytes in the blood. But when virulent cultures of the same organism were inoculated there was a marked reduction in the number of leucocytes, which reduction became more and more apparent toward death.

In one of the last Croonian lectures, delivered by J. Burdon Sanderson before the Royal College of Physicians, he draws attention to the difficulty of supposing that in the spread of traumatic erysipelas the invading myriads of streptococci can be effectually opposed by the leucocytes which follow in their rear. A similar difficulty exists as regards the more specific infections. If phagocytes are to be looked upon as policemen whose business it is to watch over the safety of the organism, they ought to present themselves in force wherever and whenever there is great danger. Now Metschnikoff's own observations, confirmed as well by his supporters as by his opponents, show that this is precisely what does not happen; that is, that although it is perfectly true that leucocytes take part in the local reaction to which the entrance into the organism of many pathogenic microbes give rise, they neither appear at the place nor at the time that they are wanted. (Burdon Sanderson adds, that in this respect they are like policemen.) Indeed, if we compare the reaction which a mitigated culture produces in the subcutaneous tissue of a healthy animal with that which is evoked by a virulent one, we find that the main point of difference is that whereas in the former case, where there is no danger, our policemen assemble in force, they are either entirely absent or appear in scanty numbers where danger is imminent. It is not the aim of this report to give the literature on the subject of the function of leucocytes, nor of their rôle in inflammation, nor of their chemotaxic relations, but simply to indicate valid reasons for believing that Metschnikoff's theory of phagocytosis is not sufficient to explain immunity. E. Klein, M.D., F.R.S., in a lecture at the Royal Institute in February, 1891, made the following remarks: "It must seem very extraordinary that the presence of phagocytes should be really a true explanation of the refractory state of the frog toward anthrax, considering that the bacilli, like other minute particles, when injected into the dorsal lymph-sac, would be absorbed and brought into the circulation in a few minutes, nay seconds, at any rate some hours before the phagocytes have got into the lymph-sac in sufficient numbers to battle with the bacilli." He continues: "It is important to say, 'in sufficient numbers.'" The question of importance for the theory of phagocytosis is obviously one of numbers of leucocytes present. Frogs kept in the aboratory never contain more than a few drops of lymph in the lymph-sac, and the number of lymph-cells, though great in the microscopic specimen, is insignificant, if compared with the enormous numbers of spores and bacilli that can be and have been injected into the lymph-sac of such frogs without producing anthrax."

The point is not whether there are numerous leucocytes present in the lymph-sac—which nobody disputes—nor whether some of these leucocytes contain the bacilli—which, also, nobody disputes: but the question is, whether they are present in sufficient numbers to eat up and destroy the innumerable host of spores and bacilli injected, and whether the limited number of cells containing the bacilli is at all in proportion to the work. Surely it has never been maintained by Metschnikoff and his school that spores and bacilli are not directly absorbed and carried into the circulation, nor that the number of cells containing the bacilli is at any time great, nor that the surplus of the spores and bacilli remain quietly lodged in the lymph-sac till, many hours later, a sufficient number of leucocytes have been attracted to the seat of battle? For instance, the absorption of solid particles of dead matter introduced into the lymph-sac by no means takes place exclusively through the leucocytes. When five minims of a fine suspension of vermilion in salt solution are injected into the dorsal lymph-sac, some of the vermilion granules, a very small part, are taken up by leucocytes, by far the largest part is taken directly into the blood by means of the lymph-stream.

It is reasonable to ask those that hold that anthrax bacilli and spores introduced into the dorsal lymph-sac are destroyed by leucocytes and by these only, what they have to say of Sanarelli's extended observations[1] as to the germicidal action on anthrax bacilli of the cell-free lymph of the frog's dorsal lymph-sac, the lymph devoid of leucocytes, an action which is very constant outside and inside the sac of the frog.

Perhaps you have observed in the literature of this subject that has come to your notice that almost every experimenter speaks of the bacteria attracting the cells and not the cells the bacteria. As will be shown presently, there are many valid reasons for believing that the cells primarily do not migrate to an inflamed area because there are bacteria there, since there can be inflammation and even suppuration without bacteria, and here too the immigration of leucocytes is great and constant, and on the other hand, there are bacteria, as Gabritcheoski has shown in Pasteur's laboratory,[2] which have a marked negative chemotactic action, *i.e.*, repelling leucocytes. Fresh cultures of bacilli of chicken cholera, for example, have a negative chemotactic action on the leucocytes of the rabbit. Nevertheless, it is somewhat difficult to explain why if the cells attract the bacteria, thousands of cells should migrate to the spot where micro-organisms are present, whereas if the bacteria attract the cells the emigration of leucocytes can be readily explained. To answer this question, it must be maintained first of all that in the first place, as Councilman has proven, bacteria are not at all essential to make up an inflammation, and from this it may be gathered that the bacteria are not essential to the migration of leucocytes, as this occurs in every, even sterile, inflammation.

In Welch's experiments of the organization of blood-clots it was stated that one of the first changes that occur is the penetration into the clot of polynuclear leucocytes. The products of disintegration of the physiological elements of the clot seem to attract them, and although many more leucocytes enter the clot when it is infected, this, according to our view, does not occur because there are bacteria in it, but because the latter set up a greater degree of decomposition in the clot, and the increase in chemical products of this tissue disintegration attracts a larger number of leucocytes. But why do the leucocytes really seem to accumulate around and in an inflamed area? For three main reasons: 1. A physical one; 2, a chemo-pathological one; 3. a morphological one. The

[2] Gabritschcoski: Annales de l'Institut Pasteur, June 25, 1890.

physical reason has been pointed out by Schlarewsky and after him Weigert and Cohnheim. It is briefly this: The rate of the blood-flow being much reduced, the leucocytes by their physical properties stick to the sides of the vessel, the vessel-wall being morbidly altered, its tonus destroyed, they make their exit by means of their inherent active amœboid movements; or, if we wish to credit Cohnheim, by a physical process of filtration or by both.

The second reason to be given for the accumulation of leucocytes in an inflamed area, the chemo pathological one, has been derived from the experiments of Buchner.[1] It is briefly this: That wherever there is necrobiosis in the organism there too the leucocytes migrate. The products of tissue necrosis, whether bacteriological or not, attract them. Buchner has clearly demonstrated that it is not the bacteria themselves that attract leucocytes or repel them, but that it is the chemical constituents of these bacteria. He has extracted from the bodies of certain bacteria, by treatment with dilute solutions of potassium hydroxid, a substance which has powerful positive chemotaxis for leucocytes. Such products (this is important) he has obtained from the necrotic tissues themselves. He has found that the alkali albumins of the products of tissue necrosis exert a powerful positive chemotaxis for leucocytes. The third reason for the accumulation of leucocytes in inflamed areas I have called a morphological one—it is rather a morpho embryological one. All are agreed that whatever the later history of the blood-cells, they arise in the embryonic mesoblast at the same time as the heart and the blood-vessels themselves.

In inflammation we have primarily to deal with changes in the blood-vessels and blood. To consider these wholly separately, or without a perception of their unity, is a mistake that has practical as well as theoretical consequences. There can be no doubt that any crop of blood-cells must bear morphological and histogenetic relations to the preceding one. Now when we remember that the leucocytes of the blood correspond to the orignal undifferentiated embryonic cells of the mesoblast, which alone have made up the entire embryo, and which are preserved as floating organisms with a latent capacity for further development, much light is thrown on their accumulation in inflamed areas or in diseased or necrotic tissues requiring organization.

This is what I wish to bring out as the third explanation of the migration of leucocytes. They are floating, undifferentiated embryonic cells, with a latent capacity for further development. It is justifiable to presume that they are destined to aid in the reconstruction of destroyed tissue and that this may be one of the explanations of their wandering to inflamed areas, and of the attraction the positive chemotaxis that necrotic tissue has for them.

As it is well known that the undifferentiated cells of the embryo are more or less amœboid organisms, hence it is perfectly natural that their descendants should, under suitable circumstances, exhibit the properties of phagocytes under suitable circumstances; but mark you, please, this is not a case of *post hoc ergo propter hoc*, when they take in microbes in case such are present in their surrounding. From what has been said it is evident that the taking in of bacteria by leucocytes is accidental, a secondary part played by them, it is not their true function. And it is a matter of debate whether or not the bacteria force their way into the leucocytes, because the latter offer a more favorable nidus for them and because the surrounding tissue-juices, the serum, are inimical to them.

Klein is correct in saying, in the light of Buchner's recent observations, that just as certain chemical substances of the bacteria attract or repel leucocytes, so also certain chemical substances present in the cells and tissues attract or repel bacteria.

It is not a well-established fact that the spleen is an organ which pre-eminently seems to attract microbes introduced into the subcutaneous tissue, the lungs, or into the blood. In the case of malaria, relapsing fever, typhoid fever, in anthrax, and tuberculosis, is it not the spleen which is the organ "par excellence" which seems to attract and offer the most suitable nidus for the microbes? In the acute exanthemata it is the skin, in hydrophobia it is the central nervous system, and in certain forms of cancer it is the epithelial and endothelial structures. Surely it is permissible to assume that there are present certain chemical substances in these different tissues which act in a positive chemotactic sense on these various microbes, and hence make these tissues the selected nidus for their existence and growth. In the numerous instances of psorospermosis under discussion at the present time it is chiefly the epithelial cells which are mentioned as the tissues attracting especially these micro-organisms. In artificially induced tuberculosis, the tubercle bacilli are not present in the blood, but find in the cells of the spleen, of the lymph-glands, and of the bone-marrow the most attractive localities. And it seems also justifiable to assume—say, for instance, for the lymph-cells of the tonsils, of Peyer's glands, and similar superficially situated lymphatic structures, that the tissue-fluids, being inimical to the existence of bacteria that pass into the tissue from the surface, they (the bacteria) find in the cells some attraction, some chemical substance that suits them, and hence these cells, far from being the enemies of the bacteria, are, on the contrary, their places of refuge, for a time at any rate. This view of Klein's, as expressed in the London *Lancet*, No. x., vol. i., 1892, seems just as feasible as Metschnikoff's, that because these cells contain bacteria, therefore they are the chief and only bacteria destroyers. It is well established that in some acute and chronic infectious diseases the specific bacteria are lodged chiefly in the leucocytes or similar cells in which they grow and which they ultimately destroy. In Koch's mouse septicæmia, fatal in one to three days, the leucocytes of the blood are crowded with the specific bacteria, and by these the leucocytes become destroyed. In bovine tuberculosis and in tuberculosis artificially induced in rabbits and guinea-pigs, leucocytes and similar cells are the principal substances in which the bacilli settle, and in which they grow. In the tubercular form of leprosy the nodules are entirely made up of round cells in which the lepra bacilli grow, and which cells become gradually destroyed by the bacilli. In Koch's Egyptian ophthalmia the pus-cells principally contain the bacilli, and by the growth and multiplication of the latter the cells become gradually destroyed. In gonorrhœa, the gonococci are principally contained within the leucocytes and by their multiplication gradually produce disintegration of the cells. In swine erysipelas the liver capillaries contain numbers of leucocytes in which the specific bacilli are numerously present and which thereby swell up and disintegrate. Do not all these facts prove that in these diseases it is the cells which attract the bacteria? It is these cells in which the bacteria grow and multiply, and it is these cells which ultimately succumb to the bacteria.

The explanation of immunity is not to be sought in hypothetical properties of leucocytes, but in properties of the blood-plasma; for it has been shown that if an animal, susceptible to a particular disease, be first infected with the bacilli causing the disease, and then into such an animal the cell-free serum or blood-plasma of an animal refractory to that disease be injected, the development of the disease in the former animal is stopped or prevented. In other words, it has been proved beyond question that when the cell-free blood-plasma of an animal immune against a certain disease was injected into a non-immune animal suffering from the same disease the development of the disease in the latter is stopped. These assertions are based on the well-known results of the numerous and carefully conducted experiments on anthrax published by Ogata and Tasuhara, and those of Behring and Kitasato on diphtheria and tetanus,[1] and also on the important researches of Tizzoni and Cattani[2]

[1] Berliner klin. Wochenschrift, Nos. 10, 30, and 40, 1890. Also, more recently, in Centralblatt f. Bact. u. Parasit., Bd. x., Nos. 22 and 23.

[1] Deutsche Med. Wochenschr., 1890, No. 49.

[2] Centralblatt f. Bact. u. Parasit., ix., No. 21, and x., Nos. 2 and 3

with regard to tetanus. These last-named observers show that the serum of the blood of dogs made immune against tetanus possesses a powerful antitoxic action against tetanus; moreover, they have quite recently actually succeeded in curing tetanus in the human subject by injection of that tetanus antitoxin obtained from serum.

Finally, I should like to draw your attention to the recent work by Buchner and his pupils, as summarized by Buchner in the *Centralblatt f. Bact. u. Parasit*, vol. x., Nos. 22 and 23, from which it becomes very evident that the destruction of micro-organisms in living tissues is by no means accomplished by the cells of the body, and by the cells only. The experiments of Buchner and his pupils point conclusively in the opposite direction. Buchner says the first and decisive inimical influence on the infective microbes in a refractory animal, and in the living tissues, is due to the chemical action of the tissue-juices; this precedes the taking up of microbes by the leucocytes; this latter phenomenon is entirely dependent on the former, and without the former primary process phagocytosis is impossible.

In connection with the fact that inflammation can be caused in animals, without bacteria, by placing thin glass tubes containing an irritating substance in the subcutaneous tissue, allowing the wound to heal thoroughly under aseptic precautions and then later on crushing the tube by pressure from without, I was led to make a few experiments in the Biological Laboratory of the Johns Hopkins University by causing inflammation in a young dog by the injection with the hypodermic syringe of absolute alcohol, which is declared by all who have worked in this line as being a substance having a marked negative chemotaxis or repellent action on leucocytes. The skin of the dog must be shaven clear of hair, and washed with soap and hot water, absolute alcohol, and solutions of permanganate of potash and bichloride of mercury. Then the syringe, carefully sterilized, is filled with alcohol and introduced under the skin; after the injection is made the point at which the syringe entered is covered with iodoform collodion. I had no opportunity to see my dogs until eighteen hours after the injection, when a prominent lump had formed at the area of injection, very red and painful to the dog; the rectal temperature was 40.5° C. A piece of the inflamed area was excised and sectioned in a freezing microtome, the sections afterward fixed with one per cent. osmic acid in one per cent. chromic acid, stained in picrocarmine, then gradually carried up to one hundred per cent. alcohol and mounted in balsam. The number of leucocytes in such sections is very great; there are no bacteria in them nor are any to be seen anywhere in the sections.

This experiment was undertaken for my own satisfaction, to learn whether inflammations can be caused by substances with a negative chemotaxis, and whether the leucocytes are numerous in them. Indeed, after the experiment was done it occurred to me that it was quite unnecessary, as any substance capable of producing a trauma, a necrobiosis of tissue could *a priori* be presumed to cause inflammation.

Conclusions.—I have tried in this abstract to bring out the facts showing that Metschnikoff's theory of phagocytosis is insufficient to explain immunity, for the following reasons:

1. In Hess's experiments, on injection of anthrax bacilli in the lymph sac of the frog, a large quantity of bacilli and spores must necessarily be carried directly into the blood-streams, and could not possibly be taken up by leucocytes, which are shown not to be present in sufficient numbers to destroy the bacilli and spores.

2. Sanarelli has proven a germicidal action on anthrax bacilli and spores to belong to the cell-free lymph of the dorsal lymph-sac inside and outside the sac.

3. Leucocytes do not accumulate or migrate to inflamed areas because they are attracted by bacteria, since sterile inflammations and inflammations produced aseptically by substances having a negative chemotaxis abound in leucocytes.

4. Certain bacteria even exert a negative chemotaxis, *i.e.*, repelling leucocytes.

5. Mitigated cultures produce a greater immigration of leucocytes than do virulent cultures.

6. Leucocytes seem to migrate to and accumulate in areas of inflammation for three main reasons:

a. A physical reason, as pointed out by Weigert, Schlarewsky, and Cohnheim, which is to this effect—the rate of the circulation being much slowed, and arterial pressure raised, the leucocytes, by their physical properties, stick to the sides of the vessel, the walls of which, being pathologically altered, they gain exit by their own amœboid movements, or, according to Cohnheim, by a physical process of filtration.

b. The second reason, a chemo-pathological one, is derived from the experiments of Buchner, showing that necrobiosis always attracts leucocytes; the products of tissue necrosis, whether bacteriological or not, attract them. Buchner has isolated from the bacteria and from the necrotic tissues chemical products that exert powerful positive chemotaxis.

c. The third reason, a morphological and embryological one, is founded on the histogenetic relations of the leucocytes to the undifferentiated cells of the mesoblast, which alone have made up the entire embryo. The leucocytes are floating embryonic cells with a latent capacity for further development; the positive chemotaxis that destroyed tissue has for them may be partly explained by their function to aid in tissue reconstruction.

7. In the light of recent observations it is correct to assume that just as certain chemical substances in the bacteria attract or repel leucocytes, so also certain chemical substances present in the cells attract and repel bacteria. This view is supported by many examples of certain cells and tissues being loaded with the specific bacteria, in various diseases.

8. This being the case, it is justifiable to assume that the tissue-fluids, being inimical to the existence of bacteria, find in the cells some attraction, some chemical substance which suits them, hence the cells are not the enemies of the bacteria but their places of refuge. In many infectious diseases it has been shown that leucocytes and similar cells are the places where the bacteria grow, and that these cells are ultimately destroyed by them. The cells succumb to the bacteria, not the bacteria to the cells.

9. The explanation of immunity is to be sought in properties of the cell-free blood-plasma. The blood-plasma of animals immune against a certain disease, injected into a non-immune animal suffering from the same disease, arrests the progress of this disease. The blood of dogs made immune against tetanus possesses a powerful antitoxic action against tetanus. Tetanus in human beings has been cured by injection of tetanus antitoxin.

10. Buchner holds that the first and decisive inimical influence on the infective microbes in a refractory animal and in living tissues is due to the chemical action of the tissue-juices; this precedes the taking up of microbes by the leucocytes; this latter phenomenon is dependent on the former, and without the former primary process phagocytosis is impossible.

The Value of the Three "Ifs."—At a meeting of the Funeral Reform Association of England, a letter was read from Lord Playfair, of which the following is an extract: "If the coffin be of a perishable nature, if the soil be dry and porous, if the grave be not too crowded, the dead are resolved into air and into ashes as certainly in three years as they are in a furnace in the course of an hour, and in both cases without injury to the living." *The British Medical Journal* aptly says that a graveyard thus used would be a garden where the dead are resolved naturally, successfully, and inexpensively.

"When I was young we prepared students for life; now we prepare them for examinations," is a bit of truth from Jules Simon.

FRANZENSBAD—THE BOHEMIAN SPA.[1]

By EDMUND CHARLES WENDT, M.D.,
NEW YORK.

General Observations on European Spas.—On several occasions within the past ten years, but more particularly during a recent prolonged tour, I was able to give considerable time to an examination of the therapeutic methods employed at leading European spas. These methods are often complex and peculiar, and in some instances they savor not a little of charlatanism. Nevertheless, at the better class of springs, physicians of scientific attainments can generally be found, whose methods of treatment are eminently rational, and differ but little from those commonly made use of by practitioners elsewhere. Balneology and hydrology, as understood abroad, have been strangely neglected in our country. It is rather unfortunate that a certain odium of quackery still clings to these legitimate branches of the healing art. This will be removed only if more than a mere sprinkling of reputable physicians can be found to seriously interest themselves in these subjects. It would seem as if general practitioners, even at the present day, could hardly afford to plead complete ignorance of mineral springs on the score of lack of faith in their utility. For sooner or later most well-to-do patients afflicted with chronic ailments will find their way to one or another of the countless resorts now clamoring for public recognition. It is surely better for the physician to direct the steps of the patient, than for the latter to make his own selection on the strength of mere hearsay or alluring advertisements. But intelligent advice is impossible without at least a "working knowledge" of the most important spas and their therapeutic resources. There is no good reason why matters of such practical importance should remain banished from the curriculum of our colleges.

In a general way it may be stated that, those who have taken the trouble to become personally familiar with the subject, are compelled to admit the vast superiority of European spas over those in our own country. Nevertheless, this superiority is by no means due to the astonishing natural advantages possessed by continental resorts. Neither can it be attributed to the peculiar chemical composition of their springs, nor to any mysterious healing virtues residing exclusively in their waters. It is my belief that the more gratifying curative results obtained at foreign spas, are almost entirely due to the strict and systematic methods of treatment pursued there. It has taken centuries of experiment and study to bring these methods to their present degree of development. Abroad, at all the best springs, medical men insist on supervising every—even the most trivial—detail of life. Two iron rules exist. The one ensures the positive enforcement of a suitable régime, and the second brings about the complete submission of the patients' whims to the will of the physician. Thus it happens that even hopelessly stubborn people are known to give up their pet bad habits while at a European spa. Possibly the entirely new order of things, and an exclusive attention to health makes even the most obstinate willing and ready to obey orders. At all events, medical tyranny, otherwise intolerable, is meekly borne at the spa. If we could substitute for the happy-go-lucky American way this painfully precise European system, our own mineral-water stations would soon attain a celebrity unexcelled by foreign resorts. Again, at all reputable continental spas, the doctor plays first fiddle and the hotel-keeper is relegated to his proper place among the drummers. This little peculiarity we might also, with advantage, borrow from our transatlantic cousins.

As to the general question concerning the utility of spas, it is too late in the day to dismiss the subject with a shrug of the shoulders. Yet it may be admitted that, if mineral waters, baths, etc., could be taken at home in the same way in which they are employed at special resorts, equally good results might be looked for. But it is obviously impossible to supply "at home" the necessary environment, and secure that complete devotion to "a cure," which are and always will be obtainable at every properly managed spa, and there only. Invalids will, therefore, continue to take long journeys in order to reach out-of-the-way places, where they may reasonably hope to secure greater relief from suffering than by merely drinking a prescribed number of goblets of imported or artificial mineral water, while still subjected to all ordinary home influences.

In the present communication I intend to give some account of a spa which appears to be much less known in America than in the interests of suffering humanity it deserves to be, namely Franzensbad, in Bohemia. Every physician has heard of Carlsbad, and Marienbad is only a little less famous. But Franzensbad has hitherto received very scant notice at the hands of the profession in our country. For this reason I shall go into somewhat greater detail than would otherwise have seemed necessary.

In Europe the place is universally recognized as belonging to that galaxy of famous Bohemian spas, of which Carlsbad shines as the bright particular star. Personally I am convinced that for quite a number of morbid states a course of treatment at Franzensbad is safer and far more likely to prove beneficial than the indiscriminate drinking of the waters at overcrowded Carlsbad. Without any desire on my part to belittle the striking effects witnessed at the latter place, I may state that I received an impression that Carlsbad is regarded, even by many physicians, too much in the light of a possible panacea for every variety of troublesome chronic disorder. It may be well to remember that the maxim "if it does no good it can do no harm" is decidedly not applicable to Carlsbad. The cure there is too serious a thing to be lightly undertaken.

Satirists and other keen-eyed observers have pointed out that our republican citizens are wont to repair in large numbers only to the aristocratic and fashionable spas. This is true. And I cannot conscientiously recommend Franzensbad to those who are looking merely for the distractions belonging to "high life" at international resorts. Franzensbad is a place for invalids, not for lion hunters and pleasure seekers. On the other hand I had ample opportunity in the six weeks which I spent there, to become convinced that real patients of various classes are more likely to be cured at this dull and quiet Bohemian village that at many of the more fashionable watering places.

Special Features of Franzensbad.—The little town (more properly village) of Franzensbad is situated in a fertile plateau of German Austria, known as the Egerland. It is only a short distance from the ancient and picturesque city of Eger, in the northwest corner of Bohemia. The spa itself is at present quite accessible, being a railroad station, where all local and express trains make a stop. Through tickets are issued from the principal European cities, and the vexations of frontier baggage-examination have been reduced to a minimum by special arrangement with the authorities.

The native population numbers only about two thousand. But from eight to ten thousand visitors annually go there for treatment.

Few Anglo-American Visitors.—Coming as I did from Carlsbad, where every fifth or sixth person one meets speaks English, or at least tries to do so, the infinitesimal proportion of Anglo-Americans at Franzensbad could not fail to present a striking contrast. In addition to the large German and Austrian contingent, Russians, Hungarians, Poles, Spaniards, Italians, and Frenchmen were fairly well represented in the motley assemblage of patients frequenting this spa. But the Britisher and the Yankee, with their wives and their daughters, were conspicuously absent.

Poor Hotels.—It must be allowed that the hotel accommodations provided at Franzensbad are not up to the American idea of comfort and elegance, whereas at Marienbad and Carlsbad, even very fastidious tastes can now be gratified. It is necessary to take this evident

[1] Read before the Manhattan Medical and Surgical Society, May 27, 1893.

drawback into consideration before advising very exacting patients to go to Franzensbad, if one would avoid disappointment. For actual disgust of one's quarters may in great measure neutralize the good results otherwise obtainable at a given watering-place. Evidently the Franzensbaders have not yet learned, like their more enterprising neighbors, to cater to the tastes of luxury-loving Americans. However, I was assured that improvements in this direction were seriously contemplated in the near future, and I trust the assurance may turn out to be more than an idle promise. At the present time most patients rightly prefer to live in lodging-houses, where fairly comfortable quarters are provided. Eatable meals are procurable at the numerous inns and restaurants.

It may be mentioned here that, contrary to current belief, exorbitant charges are not made at Franzensbad. The expense of "a cure" there is fully one-third less than at Carlsbad, the latter place being about the dearest spa in Europe, according to my experience.

An Agreeable Climate.—Franzensbad is fortunate in the possession of a moderated mountain climate which is altogether agreeable during the season, *i.e.*, from May to the end of September. The air is pure, bracing, and refreshing. It is credited with being specially rich in ozone, but I was unable to secure reliable data in substantiation of the latter claim. At any rate, the nights are always cool, even if the mid-day heat has been uncomfortable. It is only fair to regard the excellent climatic conditions as a contributing factor of no mean importance in the surprisingly good results obtained at this spa in most anæmic disorders.

The neat and trim little town lies at an elevation of about fifteen hundred feet above the level of the sea. It is freely exposed to the winds, but the streets are wide and for the most part planted with trees. There are in addition a number of really fine parks, so that there is little annoyance from dust. The nature of the soil is such that moisture quickly disappears, yet the atmosphere is never excessively dry. Although built in an uninteresting plain, richly wooded hills are found at no great distance from the spa; and beyond these there are visible spurs from the Erzgebirge, Fichtelgebirge, Böhmerwald, and other mountain ranges. Still, the striking picturesqueness of Carlsbad and Marienbad will be looked for in vain at Franzensbad.

Satisfactory Sanitary State.—The general healthfulness of Franzensbad is unquestioned. The authorities exercise due vigilance in the suppression of all nuisances, except the indoor cabinet nuisance. Smells from the latter source are permitted to befoul the atmosphere of many hotels and lodging-houses. But the average foreigner (always excepting the hydrophilous Briton) appears to thrive on offensive odors. By ventilating one's bed-rooms, danger from this source may be effectually avoided. The ordinary drinking-water is not above reproach, but as almost everbody takes the mineral waters, not much importance attaches to this point.

It is claimed that the famous ferro sulphated peat-bogs which almost surround the town have potent antiseptic powers. Be this as it may, Drs. Fellner, Klein, and other leading practitioners all agreed in assuring me that epidemics were unknown and contagious maladies very rare in their little town.

Historical Notes.—Unlike Carlsbad, which has been famous for over five centuries, the reputation of Franzensbad is of comparatively recent date; in fact the place has acquired international celebrity only within the present century, although the natives had used the springs as early as 1565. In 1793, by imperial edict of Francis II., the place was called Kaiser-Franzensbad. Only a few springs were known at that period. New ones continued to be found as late as 1879, when the Natalie-quelle was discovered. In the time-honored local chronicles it is related as an extraordinary fact that the earliest attempt to establish a spa at Franzensbad (which has since been chiefly patronized by the weaker sex) was frustrated by bands of angry women. Indeed the opposition of the Amazons became so boisterous and destructive that the military had to be called out to suppress the howling rabble.

The Cure.—In regard to "the cure" at this resort, it is mild, gentle, and reconstructive, thus differing entirely from the violently alterative reduction methods practised at other Bohemian spas.

A course of treatment at Franzensbad consists essentially in drinking the mildly aperient chalybeate waters, in mineral-water and mud baths (or mud poultices), in moderate daily open-air exercise, or a modified rest cure, and in a somewhat restricted though generous dietary, calculated to aid in building up the general health.

As adjuncts to this simple mode of treatment, the usual hydrotherapeutic and electrical measures are employed, massage is given, and special local indications are fulfilled.

So far as my observations extended, there was less extraneous humbuggery than one would expect at a resort so crowded with hysterical women. That profound psychical impressions may and do result from the various manœuvres to which patients are subjected, is of course well understood, and may be part of the cure. But the transcendentalism of faith-cure methods has found no congenial home at Franzensbad.

The Springs.—The twelve springs of Franzensbad are quite similar in chemical composition.[1] They supply waters which are cold, clear, and sparkling. Their temperature varies only between the limits of 50° and 53.5° F. To the taste they are agreeably acidulous or feebly saline. Several of the springs, however, have a slightly styptic, inklike taste, which is not altogether pleasant. As will be seen from the subjoined table, the main ingredients are: 1, iron; 2, sodium sulphate (Glauber's salt); 3, sodium chloride; 4, alkaline carbonates; 5, free carbonic-acid gas.

Analysis of the Franzensbad Springs.*

* The springs were discovered and utilized in the order here followed.

[1] Die Heilmittel von Franzensbad. Herausgegeben vom Vereine der Aerzte in Franzensbad. 1892.

It is customary to arrange these springs into two principal groups, of which the first contains those waters which are credited with being in the main "solvent" and "absorptive" (lösend und resorbirend), whereas in the second group the tonic chalybeate principle predominates. It is unnecessary to enter here into all the refinements of subdivision and classification. These rather fanciful procedures can be safely intrusted to the zeal of local practitioners. It may be mentioned in this connection that while I have no desire to disparage the earnest and honest efforts of "bath-physicians" in general, the outsider can never quite rid himself of the notion that in the matter of specific indications for particular springs they are very apt to overdo things. It may be good business, but it looks like poor science. So, too, it is my belief that their long lists of indications should be scaled down to reasonable proportions. It is impossible not to agree with Dr. More-Madden, who says that "nearly every mineral water that is now referred to, although unquestionably possessing therapeutic virtues, in suitable cases, has been belauded by the local panegyrists by whom remedial properties are assigned to its employment in almost as many and as different classes of disease as could be included in the encyclopedic advertisement of a *fin de siècle* patent medicine company."[1]

Most of the Franzensbad springs are used for drinking purposes. For bathing and douching the Louisen, Loimanns and Stahlquelle are chiefly employed. The various thermal establishments are complete in every detail and are supplied with modern apparatus for hydrotherapy.

The Mineral Water Baths.—It is claimed that the tonic and invigorating effects of these baths are actually due to the specific action of the ferric and other salts contained in them. After repeated personal trials of the various kinds of baths employed, I prefer to believe that the carbonic-acid gas which collects in small bubbles on the skin, producing a decided redness, coupled with a prickling sensation, has much more to do with their efficacy than the presence of numerous salts. To my mind cutaneous stimulation adequately explains the nature of their efficacy.

Two methods of giving the baths are employed. The first is that of Pfriem (called here Louisen, or mineral bath), in which the cold mineral water is allowed to fill the tub, and is then raised to the proper temperature by conducting steam into it. Much gas escapes by this method.

The second is the Schwarz-Reinitz process (called steel bath at Franzensbad). By this method the hot vapor is conducted through coils covered by a sieve-like metal plate, thus giving a double bottom to the tub. This indirect application of heat insures a great richness in carbonic-acid gas. These "Stahlbaeder" are popularly called champagne baths.

The Gas Baths.—At the Polterbrunnen a vast quantity of carbonic-acid gas escapes with a rumbling noise. The gas is collected in a wooden receptacle whence a pipe conducts it into tubs and depressed compartments, in which patients seat themselves without undressing. The head is, of course, made to project above the level of the toxic gas. In various neuroses and in amenorrhœa, but especially in sexual frigidity and impotence, the local practitioners claim surprisingly good results from these gas baths. That they act as potent excitants to the peripheral nerve-endings and may, through reflex channels, affect the central organs, must be freely admitted. But of their alleged beneficial action in diseases dependent on organic lesions, I saw not the slightest evidence.

The Mud Baths.—These peculiar baths constitute the special feature of Franzensbad. To them the place owes its chief éclat. Vast deposits of the peat, or "mineral moor," are found to the west of the town.

These peat-bogs have a depth, in some places, of nearly fifteen feet. Robbed of its saline iron mud, this little Bohemian resort would speedily lose its world-wide reputation. But it is estimated that there is enough to go around for several centuries longer. In fact, some writers maintain that an inexhaustible supply exists, and that there is no danger to local interests from the increasing quantities of peat dug out for exportation.

[1] The Medical Magazine, January, 1893.

At Franzensbad mud-bathing has indisputably reached the climax of development. Now, it may sound like an Irish bull, but it is none the less literally true, that a person who has never taken a mud bath does not know what a mud bath is. I took two.

The general appearance of a tub full of Franzensbad peat, as prepared for a bath, is not exactly inviting. Perhaps the old English description of an ink-stained bread poultice is as apt as any. And yet it is well known that even fastidious and timid women, who are at first utterly repelled by the disgusting sliminess of this substance, generally manage to develop, if not some liking for, at least a tolerance of, this peculiar method of treatment.

With reference to the extraordinary beneficial virtues attributed to bog or peat earth, a few remarks will suffice. After much discussion with the leading physicians of Franzensbad, an examination of the voluminous literature of the subject, and after a limited amount of personal observation, I confess that the good results undoubtedly seen during and after a course of mud baths, while they may be directly due to the power of peat, do not fairly come within the reach of scientific explanation. To my mind the whole subject is still one of empiricism.

> "Some truths are not by reason to be tried,
> But we have sure experience for our guide."

Now, experience has surely shown that Franzensbad mud baths are valuable adjuncts to treatment. And from a practical standpoint such knowledge is amply sufficient to justify their employment. I will not, therefore, weary you with a learned discourse on the various theories which have been advanced to account for their beneficial action.

The Peat.—Franzensbad mineral peat is a dark-brown or even blackish-looking turf, formed, like all similar products, by the slow decomposition of plants in the presence of various salts. The Franzensbad peat is richer in iron than any similar earth known. And the local enthusiasts naturally lay great stress on this circumstance.

Analysis of the Peat.—According to Cartellieri 1,000 parts of disintegrated moor contain the following:

I. Parts Soluble in Water.

	Parts.
Sulphate of potash	0.1958
" of soda	11.4600
" of magnesia	1.2411
" of lime	26.8954
" of alumina	7.9358
Proto-sulphate of iron	97.7803
Proto-sulphate of manganese	0.5693
Sulphuric acid of bisulphates	47.9590
Silicic acid	0.5894
Pit acid	28.1863
Other humates	29.4407
Halhydrate water	0.1859
Total	252.4390

The chief ingredients not soluble in water are silicates, humic acid, iron compounds, and vegetable remains, as shown in the following analysis:

II. Parts Insoluble in Water.

	Parts.
Sulphate of peroxide of iron	1.8463
Bisulphuret of iron	28.4522
Sulphuret of iron	3.5433
Oxide of sodium	7.1348
Magnesia	1.3743
Argillaceous earth	2.8485
Calcareous earth	1.2239
Strontian earth	0.3956
Silicic acid	2.3036
Humic acid	421.0572
Wax like substance	18.4166
Peat-resin	25.4999
Unresolved constituents	79.7352
Vegetable remains	153.7296
Total	1000.0000

Preparation of the Peat.—The peat earth is dug out by machinery during the fall months. It is spread out "to weather," a process which is one of oxidation principally. It is not harvested until the following spring, for use during the summer season. After having been dried and reduced to a crumbly mass, it is finally ready to be mixed with the natural mineral water and steam in immediate preparation for a pulpy bath.

Patients remain in the mud-filled tub for from ten to forty minutes—in exceptional cases even longer—then take a quick cleansing bath, followed by rubbing and complete repose for about one hour.

Efficacy of Mud Baths in Diseases of Women.—The mud baths are reputed to be peculiarly helpful in the various diseases of women. Indeed, Franzensbad has long been known as the ladies' spa *par excellence*. It has occurred to me that the absence of husbands and meddlesome specialists, which insures grateful physiological rest for the female sexual organs, might be as powerful a factor for good as the mysterious virtues said to reside in the local mud. I was certainly struck by the very large proportion of youngish women at this watering-place—women in whom sexual life must have been in its most active stage. Now, take an average ailing womb, and we all know the amount of prodding and jabbing it gets, the cruel stems it is impaled upon, the scrapings, touchings, curettings, packings, injections, and other fixings it has to endure during a course of "active" treatment. Suppose that you let such a multimutilated uterus severely alone for six or eight weeks, build up your patient's constitution by tonic beverages, take her away from the daily cares and frets of her household, and for a holiday occupation let her take an occasional dip in slimy mud, or have a peat poultice put on her abdomen; and you need not marvel at her quick improvement, even if the mud should happen to have fewer saline-ferruginous ingredients than that of Franzensbad.

It must not be inferred from these remarks, however, that the Franzensbad doctors altogether eschew local treatment. On the contrary, the Thure-Brandt system, electricity, and other local measures are employed in all urgent cases.[1] Yet the tendency is toward utmost conservatism consistent with safety.[2] There is no doubt that many an ovary and tube has been snatched from the impending doom of the hungry specimen jar by a timely course at Franzensbad. And the local doctors rarely mention any astonishing triumphs of mutilating surgery. Doubtless, as the laparotomy wave still further recedes, Franzensbad will be more and more appreciated. Hysterical women will then run fewer risks of castration than they do at present.

To remove some of the most important portions of woman's anatomy may yet come to be regarded as an admission of medical defeat rather than the blatant announcement of victory. In those milennial times mud may be held mightier than the blade.

Spa Life.—The general features of life at continental spas have been so often described that it will only be necessary to indicate those peculiarities which seem to belong to the one under consideration.

Everything is done in a quiet, leisurely, even lazy way at Franzensbad. There is no very early rising, no racing pedestrianism, no excessively restricted dietary, no swamping of the stomach with goblet after goblet of hot nastiness, no violent upsetment of every cherished habit of comfortable existence.

Patients here slowly sip one or more small glasses of cold mineral water in the morning hours, and a similar quantity in the early evening. Between drinks they listen to music or talk about their doctors, their husbands, and their babies. Livers, kidneys, and spleens, the very backbone of Carlsbad conversation, are only mentioned in the bills of fare at Franzensbad.

Exercise is much less insisted on than repose. And after the ordeal of a mud bath, repose certainly seems a *conditio sine qua non* of existence. The walks in Franzensbad are level, most of them are well-shaded, and all are airy. Many invalids are rolled about in comfortable chairs in the numerous parks and along the stately promenades. A "kurgemässes" dinner is a very decent and acceptable meal, with only slight restrictions. Everybody takes coffee and rolls in the afternoon. Everybody flocks together for gossip during the two daily concerts. Everybody goes to bed soon after a light supper. And at nine the little town is wrapped in profound slumber. A milder and more gentle cure (always barring the infliction of mud) than the Franzensbad one it would be difficult to devise. And therein lies its applicability to disorders that would surely be made worse by the more vigorous systems in vogue at other spas.

So it happens that young girls and little children form a fair proportion of the sick colony at this spa. Indeed, the doctors all assured me that some of their happiest results were obtained in very youthful persons. It is quite diverting to see little groups of youngsters sipping the waters with the grave and knowing airs copied from their seniors.

Indications.—The old method of distributing favors among the Bohemian spas was based on the color line. It was extremely simple and convenient. Yellow people were sent to Carlsbad, all florid, red, or purplish ones to Marienbad, and the white-faced brigade was marched off to Franzensbad.

Many of the older European physicians doubtless continue to be guided in their selection solely by considerations of complexion. But such force of habit should be discouraged; it looks like routine.

Experience has shown that benefit may reasonably be expected from a course of Franzensbad treatment in the following disorders:[1]

1. All anæmic and hydræmic disorders, such as simple anæmia, chlorosis, oligocythæmia, and even leucæmia.

2. Apart from these essential hæmic disturbances, in all secondary anæmias following loss of blood from whatever cause, or when due to impaired nutrition, or as a sequel of various acute febrile affections, such as influenza, pneumonia, typhoid fever, and diphtheria. Scorbutic, scrofulous, rachitic, and hæmophilic tendencies, and similar constitutional derangements.

3. Certain diseases of the nervous system:
   - *a*. Functional neuroses, such as chorea, neurasthenia, and hysteria. (The local practitioners also claim to have obtained satisfactory results in epilepsy, hypochondriasis, catalepsy, hystero-epilepsy, etc.)
   - *b*. Organic neuroses, such as locomotor ataxia, the various paralyses, poliomyelitis, etc.
   - *c*. Neuralgias, such as sciatica, and tic douloureux.
   - *d*. Graves's disease.

4. Diseases of the sexual apparatus, especially in women. More particularly amenorrhœa, dysmenorrhœa, catarrhal vaginitis, endometritis, perimetritis, and pelvic peritonitis, salpingitis, oöphoritis, and all chronic exudations and inflammatory deposits within the pelvis. (Strong claims are also made in behalf of uterine displacements, the tendency to habitual abortion, sterility, delayed puberty, and sexual frigidity.)

5. Chronic inflammatory affections with effusion, such as pericarditis, pleurisy, and perityphlitic deposits, gouty and rheumatic swellings; also anchyloses, periarticular and muscular nodes, periostitic swellings, thickenings after fractures and dislocations, and the like.

6. Catarrhal affections of the upper air-passages, especially when on an anæmic basis, gastro-intestinal disorders (more particularly when accompanied by constipation and anæmia), blennorrhœal diseases of the organs of generation and their sequelæ, the early stages of chronic Bright's disease, and most lithæmic disturbances.

[1] It is proper to state that the writer has, perhaps somewhat arbitrarily, curtailed the long list of diseases for the relief of which Franzensbad is said to be specially useful. Nevertheless, even as it stands, the list includes disorders for the cure of which other spas enjoy an equally high reputation.

7. Finally, Franzensbad is a good place for so-called after-cures, following the more energetic and depressing measures employed at other spas.

MARTIN'S OPERATION ON THE PERINEUM.

By WILLIAM S. CHEESMAN, A.M., M.D.,

Auburn, N. Y.

Fellow of the New York Academy of Medicine.

Though an excellent translation of his "Frauenkrankheiten" has been published in America, Martin's operation seems not to have won on this side the water the following it deserves. No one can witness the results obtained by Martin himself without being struck by their excellence. Whoever has watched him operate on case after case, in a single morning, and has had the opportunity accorded to his private students of seeing the ultimate results of his work, will, though he may not follow Martin in all its details, agree that the operation deserves wider fame.

As to steps and technique. Martin's antisepsis is of a very strict sort. The patient has a bath; mons and vulva are shaved, scrubbed with soap and water, and douched with bichloride solutions, the vagina is scrubbed with the fingers and douched. Irrigation by a stream of weak bichloride constantly plays over the denuded surfaces. The hands of operator and assistants receive a searching disinfection. Martin wears a rubber apron covering his very considerable person from neck to feet. Over this douches pour, and are conducted into a receptacle beneath the table. The first step, when endometritis is present, is a curettage of the uterus incomparably thorough and energetic. With his own strong curette, Martin removes, or endeavors to remove, the whole endometrium. The cavity is then irrigated with a five per cent. solution of ferric persulphate.

This procedure at first glance seems rough, and the grating of the steel on the uterine wall is not pleasant to hear. But the curette's edge, though narrow, is not sharp, and when curetting is to be done, let it be done thoroughly.

If laceration or hypertrophy of the cervix exists, an amputation flush with the upper end of the tear, and closely after Schroeder, is now done. This strikes the average American as often a ruthless and needless procedure. And in amputating, as a routine, where closure of a tear fulfils the indication, few, even in Germany, follow Martin. Machenrodt was recently sharply criticised in the Berlin Gynecological Society for claiming this as needful to restore the uterus to its natural size. Doubtless in cases of great hypertrophy and elongation amputation is indicated. In cases of simple cervical laceration conservative operators will merely close the rent.

The next step is an anterior colporrhaphy, which disposes of the cystocele (Fig. 1). The anterior extremity of the

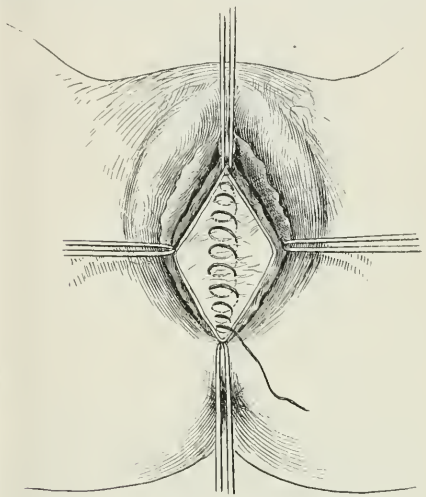

Fig. 1.—Anterior Colporrhaphy. *a*, Running catgut suture.

surface to be removed, viz., the swelling beneath the opening of the urethra, is seized with bullet-forceps and held upward by an assistant. The posterior end, close to the cervix, is caught by a second, drawn out of the vagina, and stretched downward; while the lateral limits are held similarly. When all four are on the stretch the field of operation is admirably exposed. For all denudations Martin employs the knife; and, after one has accustomed himself, more rapid and easy work can be done with it than with scissors.

Then comes a running catgut suture known as the "Etagenaht." Starting at its upper end, a portion of the raw surface on either side of the middle line is caught by the needle. These are drawn together by the suture, and the needle then takes up some of the surfaces next below, and so on from one end of the denudation to the other. The two sides of the wound are thus coapted firmly in their deeper portions, and one story, or *étage*, is finished. A second is then built by catgut carried back over the same course. This usually closes the wound up to the mucous membrane, which is now sewed together by the same catgut, and this step is completed. The advantage of this method of closure is the avoidance of all dead spaces, cavities where fluids may collect and abscesses originate.

The second step is the most original feature. It is a double lateral elytrorrhaphy (Fig. 2). The denudations, made an inch or so apart on either side the columna rugarum posterior, are two long narrow triangles in form, their bases on the crest of the rectocele, their apices just behind the cervix. Each is closed by a running suture as soon as made.

Martin thus explains their purpose and theory: "My plan of operation is based closely upon the physiological conditions existing in the vagina, and occurred to me

when viewing Freund's drawing of perineoplasty.[1] Freund calls attention to the fact that in the H-shaped figure of the vaginal lumen (seen in section), the thicker masses of tissue are to be found in the anterior and posterior vaginal wall, the side walls being remains of the Müllerian ducts, whose coalescence in the median line produces there these masses of tissue rich in fibrous elements (columnæ rugarum posterior et anterior), which are to be plainly felt and seen so long as frequent cohabitation and child-bearing have not smoothed out their folds. But even when the rugæ of the vaginal mucous membrane have disappeared, we are still able to demonstrate, upon section, the existence here of these fibrous collections. With these facts in mind. I make my denudation on the posterior vaginal wall in such a way as not to destroy

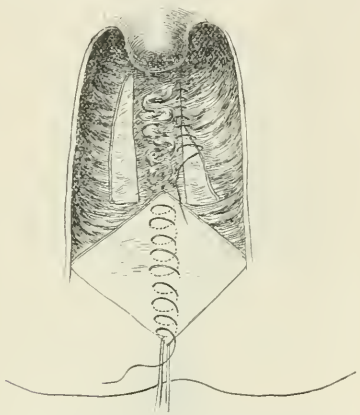

FIG. 2.—Posterior Wall of the Vagina, showing the Lateral Elytrorrhaphies (one partly closed) and Denudation for Perineal Body.

these fibrous elements, as happens in the method of Simon and Hegar. Rather, I employ them for the support of the new vaginal wall, by denuding on either side of them to about half the height of the lateral wall. Thus in the posterior vaginal wall two raw surfaces are made, which about correspond to the inferior fold of the remnant of Müller's ducts; and when these surfaces are sutured the edge of the columna rugarum posterior lies at about half the height of the side-walls, while the columna posterior itself, with its thick mass of connective tissue, is raised. It is in one's power to adapt this elevation of the posterior wall to the needs of each case."

Now, whatever bearing upon operations for uterine and vaginal prolapse pre-natal structures, like Müller's ducts, may have for the German mind, there can be no doubt to anyone who has seen the practical results of this double lateral posterior elytrorrhaphy, that it is a capital method of taking a tuck in a relaxed vaginal tube. And in cases of injury to the pelvic floor with vaginal extroversion, it seems absolutely needful that some such taking up of redundant tissue be practised. The mere construction of a perineal body does not meet the indications. The outrolling walls must be braced in their entire length. Martin's double posterior, combined with the single anterior, colporrhaphy gives lines of support such as whalebone gives to a waist, or buttresses to a wall.

The final step in Martin's operation is the construction of a perineal body. Bullet-forceps grasp the four corners of a quadrilateral (Fig. 2) viz., the middle of the rectocele, the points at either side whose coalescence is to form the posterior vulvar commissure, and the lower angle of the laceration. These are stretched widely apart, the figure sketched with the knife, and denuded. The catgut "Etagenaht" follows, at least four *étages* being usually required to close the wound.

When the laceration extends into the rectum, the plan differs in no essential respect. The denudation is carried down around the rectal tear to the mucous membrane of the bowel, and the continuous catgut closes this on its first trip down the middle of the wound, the needle being carried to, not through, the rectal mucous membrane.

Of course the above method hinges on the sterilization of catgut. Martin's mode of preparation is: Wind on spools (glass). Soak six hours in watery solution of sublimate 1 to 1,000; then twenty-four hours in oil of juniper, two parts, and absolute-alcohol, one part. Remove to fresh solution of the same, and keep indefinitely. Not to be used till after two weeks. When we consider that Martin uses catgut, so prepared, for all plastic work and for all intra-abdominal ligatures and sutures, it will be seen that this method of sterilization has been well tested.[1]

My own experience of Martin's operation comprises some ten cases, of which two were for complete laceration. All presented the usual cystocele and rectocele, frequently with endometritis, and laceration and hypertrophy of the cervix. Severe metrorrhagia had occurred in two cases, and was the cause of the patient's seeking advice. In every case a thorough curettage was practised; the cervix, if hypertrophied, was amputated; if not enlarged, any tear was closed by Emmet's method. The other steps were taken as prescribed by Martin.

All of these cases, with one exception, healed satisfactorily. In that case the temperature rose to 101° F. the evening of the operation, and a diffuse cellulitis of the perineum and buttocks ensued. For this my own carelessness was responsible, as I had allowed the patient to be placed in a ward where was a woman with discharging sinuses from tubercular bone disease. Every antiseptic precaution was, as usual, taken at the operation, but infection followed. Part of the operation wound opened and discharged, but the greater part held, and under irrigation the suppurating surfaces became healthy, adhered, and the final result was as excellent as if primary union had occurred. In one case, that of a lady much depreciated in nervous tone, while the wound healed beautifully, severe hysterical symptoms ensued three days after operation, and involved a prolonged convalescence.

The final result in these cases was all that could be desired. Some of the patients were working-women, and had been unable, without great suffering, to get through their daily tasks. They are now able to work with comfort. In the cases of metrorrhagia the hemorrhage was permanently checked by the curettage. Where uterine prolapse had been present in moderate degree, it was so much relieved that discomfort was no longer complained of. In one case the operation has not cured a severe uterine prolapse, but a pessary is now easily and effectively worn. In this case, as in others of equal degree, I think Martin's operation should be supplemented by ventro-fixation of the uterus.

In the cases of complete laceration the first operation was a frank failure. I took Martin's printed advice, and moved the bowels on the fifth day, when, despite all care, the softened catgut sutures gave way and ruined the sphincter. With commendable courage this lady underwent a second operation. Her diet consisted of animal broths exclusively. These make soft fecal masses, while milk forms huge curds that are difficult to soften, and tear the sphincter. The bowels were not moved till the third week, when she had a soluble, easy stool, leaving a perfect sphincter. In the second case the bowels were constipated till the third week, and though a few of the stitches midway between anus and fourchette suppurated, the ultimate result was perfect.

I have also employed the running catgut in three cases of acute incomplete, and one of complete, laceration of the perineum in confinement. This latter occurred in a woman with small vulva and rigid perineum, in spite of all my efforts to prevent it. All of these cases got prim-

[1] Naturforscherversammlung, Wiesbaden, 1873

[1] In preparing catgut for my own use, fat is dissolved out by ether; then comes a soak in a 1 to 1,000 solution sublimate; then in alcohol; then in oil of juniper; then it is boiled in alcohol two hours, in which it remains till used.

ary union and a perfect functional result. I prefer the buried "Fortlaufende Catgutnaht" to all other methods of closing lacerations primarily.

Clinical Department.

DYSMENORRHŒA.—A CASE THAT TROUBLES ME.

By HORATIO R. BIGELOW, M.D.,
PHILADELPHIA, PA.

The so called ordinary cases that consult us are often the most trying ones—ordinary simply because they are frequent and without limit as to the number and extent of the symptoms. It is a matter of regret to me, being still a student, that our medical literature should not discuss oftener these lesser studies in gynecology—which would be helpful to the profession at large—rather than consuming so much space with the mighty things which are interesting only to the purely surgical, and which things, be it said modestly and subject to correction, are becoming repetitious.

The case that troubles me is one of dysmenorrhœa. The symptoms that I have only partially subdued are pain and insomnia. Briefly the history of the case, which was referred to me by Dr. Wilson, of Woodbury, N. J., is this:

Mrs. P——, an anæmic blonde, without children and under thirty years of age, for some years married, has never been without pain during the menstrual period from the time of puberty. During the last two years it has increased in violence. She is regular as to time and amount.

The first day is natural and painless. On the second day the flow stops, and an intense indescribable pain near the left ovary, and descending to the knee of the same side, sets in and lasts for two days (yielding only to large hyperdermatic injections of morphia); then the flux re asserts itself and continues for a week. During the period the patient is confined to her bed or to the house for two weeks. She is exhausted and thin, has an intractable insomnia and no stamina. She was in danger of morphinism when sent to me. Her physical condition is just what might be expected, depression and melancholia having the upper hand. Eighteen months ago she consulted an eminent professor of obstetrics here, who dilated the cervical canal, but to no purpose.

Status Præsens.—An examination of a drop of blood shows a diminution in the normal amount of red corpuscles. Urine, normal; reflexes, normal; weight, 119 pounds; tongue, red and flabby; respiration, normal; pulse, 90; vagina, narrow; uterus, retroverted, first degree; ovaries made out with difficulty, but so far as I can ascertain after several very careful examinations, normal; tubes, normal. There is very slight tenderness in the posterior cul-de-sac, and pain is complained of when the body of the uterus is tilted up on the finger. It is utterly impossible to pass even the smaller sound beyond the internal os. The atresia is perfect. Pressure here by the sound sets up the characteristic pain which is making the patient miserable.

Treatment.—Small insulated sound in the cervical canal connected with the negative pole of the galvanic battery. A large clay pad on abdomen connected with the positive pole, a current of 10 m.m. to start with. Vagina washed out with a one per cent. lysol solution before the operation, and uterus and vagina washed out after. I may mention here that the endometrium was very sensitive to the sound, but the discharge was inconsequent. Séance, five minutes, well tolerated, patient resting for two hours after each sitting. As there were only ten days between the period that could be depended upon, I gave the static bath every other day, and dilatation was practised three and four times between the periods. Porter was ordered. The first flow after this inauguration was attended with less pain, but the insomnia was as bad as ever. For two weeks the patient did not leave the house, and was much exhausted. Treatment was recommenced on the same lines. I found the canal closed as tightly as formerly. I gave chloralamid to induce sleep, and ordered suppositories of cannabis indica, one every day, commencing with the period. This plan of treatment was continued for three months. Nothing got better but the insomnia, and this always yielded to the chloralamid, which acted happily, leaving no ill consequences. Nothing subdued the pain but the morphine injections. Six weeks ago, after thorough irrigation, I dilated rapidly and used a glass-stem pessary. Before doing so I made as careful a diagnosis as I am capable of making, but discovered nothing other than that of which I have written. The static baths quieted and acted as a tonic. She sometimes slept for an hour after them. Everything has been done to enrich the blood-supply. Plenty of out-of-door exercise, milk, eggs, and beefsteak; albuminate of iron, first brought to my notice by Dr. Grünberger, of Carlsbad, and alcohol baths. The last period was worse than any before it. She is now overdue; has pain in the region of the uterus, and a heavy head. The abdominal pain may result from the dilating. The canal is much more permeable at some times than at others. The stricture is more spasmodic. What have I gained? Only this. The insomnia yields to the chloralamid, and this permits her general health a chance of sympathizing with the iron and tonics generally. The endometrium is less sensitive, owing to the electric curetting and to the intra-uterine lysol irrigation. Her appetite is better, and she has more strength to resist pain. What am I to do farther? I do not know. An operation? Not if she can get well without it. I am no great lover of iron. In my hands it has oftener done harm than good. In Scwalbach, the waters caused headache and other unpleasant symptoms. Dr. Grünberger prescribed this form of iron—the albuminate—for my wife, and it did all that he expected. It had escaped my memory until reminded of it by this case. It assimilates well, and is doing its tonic work. If this dysmenorrhœa is due to anæmia, then the iron is, of course, indicated. Perhaps the faultiness of the blood-supply acts as an irritant to a hyperæsthetic condition of the membrane at the internal os, and causes a spasmodic stricture. In a general sense it is understood to be significant of ovarian trouble when that peculiar leg pain exists, and yet, in this case, there is nothing abnormal to be made out in either ovary. Would an operation be justifiable under such circumstances? Is iron indicated, and is this the best form of it to administer? Is the insomnia to be combated with hypnotics, and for how long?

1716 Chestnut Street.

Influence of Ablation of the Spleen on the Microbicide Power of the Blood.—Dr. Montuori has published the results of some observations on this subject. His method was simply to remove the spleen, preferably from dogs and rabbits, and after a given time to test the bactericidal power of the blood of the animal. His conclusions are as follows: 1. Removal of the spleen is followed by a manifestation of a gradual diminution of the bactericidal power of the blood. This power generally remains about normal for the first fifteen days, being gradually lost between the fifteenth and the thirtieth day; 2, after a time varying from two to four months the bactericidal power gradually returns, and is completely restored in about four months; 3, these effects take place more rapidly in young than in old individuals, and more rapidly in rabbits than in dogs; 4, the germicidal substance is, in Montuori's opinion, of the nature of a ferment; 5, after splenectomy the blood loses not only its germicidal power, but also its power of destroying the corpuscles of other animals introduced by transfusion; 6, the same applies also to the bactericidal powers of the other juices of the body.—*British Medical Journal.*

Progress of Medical Science.

The Pathogeny of Diabetes.—Drs. Chauveau and Kaufmann regard the pathogeny of diabetes as one of the most important subjects in progressive general physiology. The glycemic function plays a most important rôle in the nutritive activity. The blood studied in a fasting subject constantly contains glucose. The subhepatic veins contain most of the sugar of the economy, and the venous blood of the general circulation is always less rich in glucose than the arterial blood. This physiological sugar is, therefore, in an incessant state of formation and destruction. It is formed in the liver (Cl. Bernard) and destroyed or transformed in the capillary networks intermediary between the arteries with red blood and the veins with black blood (H. Chauveau). It is this condition of the blood which is expressed by the term glycemic function. This is, without doubt, an improper term because it implies a manifestation of activity, a movement, while it in reality is applied to a sort of static state. The true glycemic function consists in active nutritive changes which prepare, transform, and utilize the sugary materials of the blood. This state of the blood is commonly designated by the term glycemia. The terms hyperglycemia and hypoglycemia are also readily used, applied to cases of exaggeration or of diminution of the normal or physiological glycemia. The glycemic function, therefore, represents the ensemble of acts which tend to maintain, with the permanence of the glucose in the blood, an equilibrium between the dispensing and the production of this substance. It is well known that glycosuria, the essential symptom of diabetes mellitus, is due to hyperglycemia, that is to say, an abnormal accumulation of sugar in the blood. But what is the immediate cause of this hyperglycemia? Does the blood become too rich in sugar because the tissues cease to appropriate this substance of the nourishing fluid for the needs of the nutritive acts which occur in the heart of the anatomical elements? Does this fluid enrich itself, or the contrary, in sugary material, because the liver turns more of it into the circulatory torrent, or even because other organs become auxiliary to the liver in the sugar-forming function? In other words, is it the consuming of the sugar which is arrested or the production which is increased when this substance accumulates in the blood of the diabetic in sufficient quantity to provoke an elimination by the renal passages? The answer to this remains still in suspense. The method employed by the authors in their effort to solve this problem rests entirely upon the results of the comparative analyses of the arterial and venous bloods of the general circulation. Three cases may present themselves; either the venous blood becomes, as in the normal state, less rich in glucose than the arterial blood, and then the hyperglycemia should be placed to the account, not of a default in the consumption of the glucose, but to an excess in its production, or the two bloods show themselves nearly equally rich in sugar, which necessarily implies a poor using of this substance in the capillary networks and places in this default of consumption the cause of the hyperglycemia; or finally, the venous blood becomes more sugary than the arterial blood, which indicates positively that the hyperglycemia is due to a production of glucose on the site in all of the tissues of the economy. To assure exactitude of the comparative results of the analyses of the two bloods the authors took care to observe: 1. That the two bloods should be gathered simultaneously and in the same amounts. 2. That they were treated exactly in the same way. 3. That the operations in general, particularly the dosage of the glucose by the standard fluid, should always be done by the same manipulator.

In the physiological state the comparative analyses of the arterial and venous bloods practised under the conditions above mentioned never fail to demonstrate that the venous blood is less rich in sugar than the arterial. This same inferiority of the venous to the arterial blood in respect to the quantity of sugar is noticed in all of the deviations of the glycemic function which are provoked by a lesion of the central nervous system. This inferiority likewise shows itself in the hyperglycemia which follows extirpation of the pancreas. The authors will demonstrate this by presenting in a future report the results of the analyses in each particular case.—*The Medical and Surgical Reporter.*

The Etiology of Malaria.—The latest addition to our knowledge of the bacteriology of malaria has been contributed by Dr. Julius Mannaberg, in a paper read before the Society of Physicians at Vienna. He divides the micro-organisms connected with malaria into two groups: (1) Parasites with direct sporulation, without syzygies; and (2) parasites with direct sporulation and with syzygies. In the first group he places the micro-organisms connected with the quartan and tertian varieties of the disease; in the second, the pigmented and unpigmented organisms found in the blood of patients suffering from quotidian ague, and also those described as occurring in the malignant forms of tertian ague. Dr. Mannaberg had observed the latter variety before Marchiafava and Bignami described them, and corroborates these observers in every detail, both as regards the appearance of the parasites and the nature of the disease produced by them. Dr. Mannaberg further demonstrated, by means of special illumination, that the younger forms of all organisms are not found in the corpuscles, as Marchiafava and Celli maintained, but, as Laveran had previously shown, are to be seen adhering to the outside of the red corpuscles. As regards the semilunar bodies in the blood of malarial patients, which have been described by several observers, Dr. Mannaberg states that in forty-three cases of "summer fever" (due to infection by the organisms contained in his second group) he found them thirty-seven times. He considers that these semilunes are formed by the coalition of two to four amœboid bodies, and states that he has been frequently able to demonstrate the approach of such bodies to each other and the subsequent appearance of a semilune. Dr. Mannaberg opposed Laveran's views that the semilunar bodies were the result of the cachexia produced by malarial poison, for he had never seen them in the blood of patients suffering from the forms of disease produced by organisms of his first group when the ague had lasted for a very considerable period, but had frequently found them within the first few days of the fever in the blood of patients suffering from the more severe forms (second group) of malarial poisoning, but in which cachexia was not marked. Finally, he considers the treatment of malaria by quinine, and maintains that the organisms are destroyed and rendered inert by the action of this drug.—*British Medical Journal.*

Virchow on the Sewage-Farm System.—At a recent meeting of the Berlin Medical Society, Professor Virchow discussed the question whether a number of cases of typhus fever which occurred in the autumn of 1891, in the district where the eastern sewage farms of the city of Berlin lie were caused by the drain water (*The Lancet*). The patients did not live on the estates, but only worked on them, returning to their villages in the evening. The estates in question were not administered by the Berlin authorities, but by farmers to whom they were let, and consequently the special sanitary regulations drawn up for sewage estates were not so strictly enforced there as on the other estates. Besides the medical men whose duty it was to report by telephone all cases of illness on the estates to the central office of the city, infectious or seemingly infectious, there were two bacteriologists whose special business it was to examine the drain water for typhus and cholera bacilli, and who have never found any. It was proved that the patients in question had drunk the water, but a temporal relation between the drinking and the appearance of the disease such as would have justified the inference that the latter was caused by

the former was not proved. The bacteriological investigation of the drain water from the fields in question led to no result; but this circumstance was not very significant owing to the length of the interval between the occurrence of the cases and the investigation. It was proved that the number of typhus fever cases that occurred at the same time in the adjacent districts further from the estates was unusually great. In view of these facts, Professor Virchow delared it highly improbable that the cases in question had anything to do with the sewage. The only previous case of typhus fever in the immediate neighborhood of the estates had been traced with great probability to the use of water from a well to which, owing to its bad construction, the water from the street gutter had access. Asiatic cholera had never occurred on the sewage estates, but there were cases of diarrhœa and cholera nostras last year during the cholera epidemic in Hamburg. The patients were inmates of the Rummelsbury Workhouse, who had been working on the sewage estates. It was noteworthy that two cases of Asiatic cholera and several of cholera nostras occurred in the workhouse at the same time. This simultaneous occurrence of more or less severe intestinal diseases with Asiatic cholera had often been observed but never explained. It was worth considering whether the Russian doctor who maintained that severe cases of Asiatic cholera occurred only when comma bacilli entered the body simultaneously with other bacteria was not right. It was necessary to subject the bacteria of cholera nostras to most exact investigation and to compare them with those found in the excreta of cholera patients. Professor Virchow assured his hearers in conclusion that there was no city in the world in which the hygienic supervision of the removal of excreta was so rigorously exercised as at present in Berlin, and that there was no reason to apprehend danger to the public health from the sewage-estate system.

Foreign Body in Hernial Sac.—At a late meeting of the Pathological Society of London (*The Lancet*) Mr. J. Hutchinson, Jr., showed the sac of a femoral hernia, the neck of which was perforated by a strong fish-bone which had evidently passed through the intestinal wall and through Gimbernat's ligament. The fish-bone had irritated the omentum in the sac and had thus given rise to symptoms resembling strangulation. No intestine was present in the sac. After removal of the foreign body (one end of which was fixed in Gimbernat's ligament) the sac and inflamed omentum were excised. The wound healed and the patient made good progress for a fortnight, when an attack of diarrhœa seems to have disturbed the adhesions and led to peritonitis, of which he ultimately died. Attention was drawn to the extreme rarity of this complication of hernia.

The Presence of a Valve at the Neck of the Bladder.—Dr. Opert states the presence of a valve at the neck of the bladder, without being associated with diseases of the prostate and bladder, is not uncommon. Mercier assumed that the condition existed only in old people, and operated with the best results in over three hundred cases.

Von Dittel denies the statement that it is not dependent upon prostatic hypertrophy, but believes that it is due to a spasmodic contraction of the prostatic ring or internal vesical sphincter.

Socin claims that the causes may be either hypertrophy of the bladder as a result of stricture of the urethra, or tumors of the bladder, etc., and as a result of the hyperplasia a bundle of transverse muscle-fibres is raised up, and possibly proves a hindrance to perfect micturition.

Eigenbrodt reports the case of a man, twenty-four years of age, who, since boyhood, had suffered from difficult urination, so much so that at times the urine could only be voided by great straining. Examination of the urethra with the ordinary catheter was impossible, as only the smallest soft instrument could be made to enter the bladder. The first examination of the urethra was followed by complete retention, and all ordinary measures to relieve the same proved fruitless. As a last resort, the urethra was opened in the perineum, a sound was easily passed until it reached the neck of the bladder, when further attempts at introduction were resisted. A small sound, with a sharp curve, was next tried, and after considerable manipulation, it entered the bladder; a catheter was then passed along this sound as a guide and allowed to remain in the wound. Two days later the patient died, and at the post-mortem the following conditions were found: The bladder was greatly dilated, and the contained urine was purulent. The urethral orifice was covered by a transverse, half-moon shape fold of mucous membrane. This fold consisted chiefly of mucous membrane; the base being somewhat thicker, contained muscular fibres, probably a part of the sphincter muscle. The prostate was normal.—*University Medical Magazine.*

Leprosy in Brittany and Morvan's Disease.—Morvan's disease consists, as is well known, in the loss of one or of several phalanges, insensibility of the fingers, hands, and arms, and disturbance of the capillary circulation. Dr. Zambaco-Pacha, who has had considerable experience with leprosy in the East, was struck by the resemblance of some of his patients to those affected with the so called Morvan's disease. In a letter written to Dr. Thibierge in 1891, Dr. Zambaco took the ground that Morvan's disease, which had of late been considered either as a form of syringo-myelia or as an independent entity, was nothing else than lepra mutilans; and that a great many, at least, of the cases described as syringo-myelia, that presented claw-like hands with atrophy of the interosseous muscles, were undoubtedly cases of leprosy of the anæsthetic type. This view was received with much incredulity, and Zambaco determined, therefore, to make an expedition to Brittany, and to see Dr. Morvan's patients. A careful investigation of the various hospitals and asylums was instituted, and inquiries were made in the various small villages about Brest as to the existence of people suffering from deformity or mutilation of the extremities. The result was the discovery of a remarkably large number of persons, chiefly belonging to the lowest class, who were affected by mutilation of the hands. Many of these persons were, without doubt, in the opinion of Zambaco, afflicted with leprosy. The mutilations of the hands were identical with those seen in leprosy, and in many of the patients cicatrices, consecutive to ulcerating tubercles, were present. Several of Dr. Morvan's patients were seen and pronounced to have leprosy of the mutilating type. In the course of Zambaco's investigations several people were encountered who possessed, in addition to the deformed hands, large ulcerated and anæsthetic areas upon the legs. Many of these cases are admitted to have presented some difficulty of diagnosis to those unfamiliar with the appearances of leprosy. But it was possible to find a certain number of classical cases of leprosy in Brittany. These were cases of tubercular leprosy of the face with leonine aspect, tubercular lesions upon other parts of the body, pigmentary and atrophic changes, etc. Several of these cases are represented by photographs, and leave no doubt that more cases of leprosy exist in Brittany than has been hitherto supposed. Zambaco emphasizes the fact that leprosy was, in former times, very prevalent in Brittany, as is shown by the remains of leper asylums, and other signs of its presence. Its existence at the present day had not been suspected, and many doubtful types of disease have been honored with new names, as Morvan's disease and syringo-myelia, most of which cases belong, according to Zambaco, under leprosy. Letters written to the various practitioners in Brittany brought a number of replies, accompanied by photographs, that left no doubt of the very considerable numbers of lepers existing in Brittany. Zambaco believes that the greater part of all the cases described as syringo-myelia and Morvan's disease are, in reality, leprosy of the anæsthetic form, sometimes in an attenuated or slightly modified form.—*Boston Medical and Surgical Journal.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, July 22, 1893.

WHAT IS PARANOIA?

We have been asked by a correspondent to tell what is meant by the much-used term paranoia. A few years ago this might have been an easy task, for paranoia then meant only a form of insanity which corresponded with what had been called monomania. But of late, systematic writers have split up and subdivided and rearranged to such an extent that there is at present hardly any agreement upon the finer distinctions of the disorder. Paranoia, however, may be considered to be a general term, covering those chronic insanities which are primary in origin, and are characterized by a systemized delusion which dominates the individual. The disease is a chronic one; it affects mainly the intellectual sphere; it is a disorder occurring in the neuropathic individuals who have a bad heredity. It is, therefore, called a degenerative form of insanity. Often the individual has been somewhat queer or eccentric from childhood. Under the stress of competition when beginning his life-work the mind gives way, and he changes from a crank to an out-and-out monomaniac, or what we now call a paranoiac.

There are a great many ways of being a crank, and there is a corresponding and natural diversity in the forms of paranoia. The subdivisions which have been made by clinicians are simple and self-explanatory. Some writers describe a congenital or original, and a late or adolescent, type, in accordance with the period at which the symptoms develop; but this is an unnecessary distinction. All agree that some paranoiacs have depressing, and others expansive, ideas. The former include the people who are constantly suspicious and worried, either about themselves or others.

We have, therefore, the types of the suspicious, the persecutory, and the sexual paranoiacs. Those who have depressive ideas form types of the religious, erotic, inventive, socialistic or reformatory, and querulant paranoiacs.

Some writers describe under the head of paranoia a form of insanity which is termed "Wahnsinn," a word which has been used and misused in so many ways that it is now practically untranslatable. It is best to drop it out of nomenclature altogether, except as indicating a form of acute insanity with excitement, hallucinations, and systemized delusions such as is often seen in asylums. It is there called acute mania, hallucinatory mania, or confusional insanity. It is not a form of paranoia.

"Verrücktheit" is another word which ought to be dropped from scientific medical literature. "Primary verrücktheit" has had about the same meaning as paranoia, but it is a popular, not a scientific name, and its use by alienists has only produced confusion.

Having got rid of these words in connection with the various forms of systemized insanity, the ground is cleared, and there need not be any trouble in the general practitioner using the word paranoia with confidence. Its usefulness lies in its broad application, covering as it does a class of insanities which are degenerative in origin, chronic in course, and characterized by systemized delusions, without much impairment of the emotional faculties or volition, except in a secondary way.

Sometimes there occurs a secondary paranoia as the result of an acute insanity, but these cases are rare.

THE TOXICITY OF URINE.

The French physicians alone seem to have interested themselves in the subject of the toxicity of urine. The results obtained have been quoted widely, but no one seems yet to have been able to reach any certain and practical conclusions. Perhaps this is due to the unpleasant and somewhat uncertain way in which the toxicity is established, viz., by poisoning small animals. If one only could catch and breed a normal rabbit whose vitality should be the standard unit, a kind of rabbit vitometer, the work would be more satisfactory. Still it continues to go on, and recently we find chronicled some new results. Thus it is stated that, from experiments on the toxic properties of the normal urine of man and of domestic mammals, carried out in the laboratory of M. Arloing, M. Guinard arrives at the following classification, starting from the least toxic: Dog, man, pig, ox, guinea-pig, sheep, goat, ass, horse, rabbit, cat. The author thinks that these experiments in comparative physiology may throw some light on the question of uræmia. The conclusions he has arrived at confirm the results obtained by chemical analysis. M. Guinard has also experimented with the urine of other animals besides those just mentioned, and he has found that the bear's comes near to the dog's, whereas the lion's and tiger's resemble the cat's. We presume that the extra toxicity of feline urine may be put into relation with the fact that cats are so liable to have fits.

Further studies have been made by Voison and Peron on the toxicity of the urine of epileptics. They conclude that the toxic action of the urine excreted before the occurrence of a fit or series of fits, is considerably below the normal. This hypotoxicity diminishes in the urine excreted during the period of recurring convulsive attacks. The urinary excretion following a series of fits is hypertoxic if the series be finished, but is not more toxic than normal if more fits are about to occur. Hypotoxicity persists after fits if the latter be followed by maniacal excitement. The urine of epileptics affected with profound mental disorder is constantly hypotoxic, though in these cases there is no departure from the rule that the minimal degree of toxicity is in the preconvulsive period. By estimating the toxicity it often is possible to predict the occurrence of a fit, whether a series has terminated, or whether mental disturbance is likely to supervene. Diminished toxicity of the urine indicates defective elimination of toxins (exciting causes of epileptic phenomena)

from the blood. Support to this view is afforded by Chambrelant's recent experiments, which showed that blood-serum of persons suffering from eclampsia is more toxic during the convulsions, but the urine is hypotoxic at that time. Intestinal antisepsis and avoidance of over-eating are some of the therapeutical measures indicated.

PROVISION FOR THE SICK AND WOUNDED ON THE NEW WAR-SHIPS.

Surgeon-General Tryon, of the Navy, has brought to the attention of Secretary Herbert a strange oversight in the construction of the new war-vessels, most of which seem to have been built without adequate provision for the care of the sick and wounded. In nearly all of these new ships the sick-bay is too small, and is tucked away on the berth-deck, where both light and ventilation are poor, instead of being located on the gun-deck above. On the New York, for example, the sick quarters are quite far forward on the berth-deck, near the torpedo-tubes. There is comparatively little light there, the ventilation is by no means what it should be, and the noise occasioned by working the torpedo tubes could not fail to exert a very prejudicial influence upon the seriously ill.

Dr. Tryon's plan for the improvement of these conditions has been submitted to the Secretary of the Navy and to the Board of Bureau Chiefs, and approved by both. He has suggested that the sick-bay on the New York be greatly enlarged and extended some distance aft, where more light and air can be obtained, and that in all new ships it be located on the gun-deck, when there is one, or well aft in those that are not provided with this deck.

The Surgeon-General very justly insists upon every care and comfort being extended to the sick, and upon comfortable and well-ventilated quarters being provided for them; and we are glad to learn that his counsels in this respect have prevailed with the Secretary, and that his suggestions will be followed.

With a Surgeon-General of Dr. Tryon's attainments, and with a Secretary willing to entertain and act upon his suggestions, we may confidently look to see the medical department of the Navy soon brought to a high state of efficiency, and kept fully on a par with the other branches of the service.

THE AMERICAN MEDICAL ASSOCIATION.

Dr. Culbertson, who has for two years edited *The Journal* of the American Medical Association, and has done it most ably and successfully, has resigned, and returns to Cincinnati to resume connection with the *Lancet-Clinic*. In his valedictory editorial some rather startling facts are told regarding the condition of the American Medical Association. We can present them best in his own words:

"The American Medical Association reached its highest membership in 1888, at Cincinnati. That city is located near the centre of population of the United States, and the meeting was boomed through the local journal. Since that date there has been an annual decline of members and of revenue from their dues. The delinquents have been quite regularly, every year, a little more than forty per cent. of the members to whom *The Journal* is regularly mailed, which indicates faulty collections. While this may be the fault of no one in particular, it is no doubt mainly caused by the distant separation of the treasurer from *The Journal* office.

"In December, 1891, when the publication of the list of members was made, we were gratified at an apparent increase in members, which was, however, more than offset by the immediate receipt from the treasurer of a list of almost five hundred names to be dropped as delinquents. The past year has witnessed an increase followed by a larger decrease."

As a matter of fact, the total membership of the Association has steadily decreased for the last five years, until it is now fifty per cent. less than it was in 1888.

This condition of things is serious, and shows that there is some inherent defect in the organization and conduct of the Association. Dr. Culbertson's remedy is to abolish the delegate system, and reorganize on a plan like that of the National Legislature. The scheme seems most impracticable, but it appears that something must be done.

The new editor, Dr. John B. Hamilton, is energetic, and may prove wise enough to devise a way of stopping the ebbing tide.

MODERN SAMSONS.

A large number of physicians were recently invited to witness the alleged miraculous feats of strength performed by an exhibition "strong man" in this city. We can hardly believe that many of the medical audience were greatly astonished at the performance. The man is undoubtedly very strong and has an interestingly huge muscular development. But the feats which he performed were not so very much beyond what amateur athletes can do. The lifting of a "human dumb-bell," *i.e.*, an iron rod with a small man at each end, is accomplished partly by a trick of strength well known to those who practise this kind of exercise. The supporting of two small horses and a very small pony on a platform was also more ingenious than masterful. It is unfortunate, at least from the medical standpoint, that the man does not go through some straightforward tests that would show in a more exact way how much he exceeds the average man in muscular power. Thus the experiments of Rey and Maréchal show that a man in good health has a power of hand pressure equal to forty or fifty kilogrammes and a force of prehension equal to one hundred and thirty-two kilogrammes.

The following are the measurements of the man, and given out as correct: Neck, 18½ inches; biceps, 19½ inches; forearm, 17 inches; chest, normal, 52 inches; contracted, 46 inches; expanded, 58 inches; waist, 29 inches; thigh, 26¾ inches; calf, 18 inches; height, 5 feet 8½ inches; weight, 199 pounds.

The most extraordinary of these figures are the chest measurements. The average man weighing 145 pounds, 5 feet 8 inches high, has a chest measurement of only about thirty-four inches. The measurement of professional athletes and pugilists rarely goes much above 40 inches.

Dr. Lapponi, the Pope's physician, says that his illustrious patient is in excellent physical condition, and ought to live for many years to come.

News of the Week.

The First Experiment in Inoculation in Russia.—On October 26, 1768, the Empress Catherine II. (*vide* a work just published by M. Waliszewski, entitled "Roman d'une Impératrice") submitted to inoculation her own august person, being the pioneer of the practice in her own dominions. At that time this was regarded as an act of heroic self-abnegation, and Voltaire expressed his admiration of the Empress in these terms: "Sa Majesté se laisse inoculer avec moins d'appareil qu'une religieuse ne prend un lavement." The preparations for the novel function were most elaborate, the operator being an Englishman named Dimsdale, summoned expressly from London. M. Waliszewski makes the following comment on these preparations: "On fait moins d'embarras aujourd'hui pour trépanner un homme ou pour lui ouvrir les entrailles." The lymph was supplied by a boy of seven named Markof. This boy was ennobled under the fancy name of Ospiennyi (ospa = smallpox), and brought up under the Empress's own tutelage. His descendants occupy at the present day a prominent position among the Russian aristocracy. Mr. Dimsdale was created a Baron, appointed Councillor of State and Body Physician to Her Majesty, and allotted a pension of £500 per annum. The present Baron Dimsdale is, I imagine, a descendant of our compatriot.—*Lancet.*

Woman Students at French Faculties.—There are at the present moment one hundred and thirty-one ladies registered as students at the seven French medical faculties. Of this number ninety-five are Russians, twenty-five French, four Roumanians, two Bulgarians, two Servians, one German, one Turk, and only one English. No one who has studied in Paris can avoid remarking the preponderance of the Muscovite element among these fair aspirants for medical honors.—*Lancet.*

The Money Expended for State Health Boards.—Dr. Archibald Dixon gives the following figures showing the amount of money appropriated each year for the State Boards of Health: Massachusetts, $111,300; Louisiana (about), $100,000; Texas, $61,000; Illinois, $49,000; Mississippi, $46,550; Minnesota, $29,000; New York, $25,000; New Jersey, $21,500; Wisconsin, $20,500; Michigan, $16,145; Alabama, $13,000; Maryland, $13,000; California, $12,500; Connecticut, $10,000; New Hampshire, $8,500; North Carolina, $5,500; Indiana, $5,000; Iowa, $5,000; Pennsylvania, $5,000; Maine, $5,000; Kansas, $4,500; Ohio, $4,500; South Carolina, $4,000; Tennessee, $3,000; Rhode Island, $2,700; Kentucky, $2,500; Vermont, $2,500; West Virginia, $2,000; Delaware, $350. This shows that only twenty-nine States expend money for this purpose. The figures, however, are very misleading. Most of the Texas and Louisiana money goes for quarantine, while the money spent by New York and other States for this purpose is not included. The amounts spent by cities for public health also exceed very much that spent by the States.

Bicycle Kyphosis.—One evil traceable to bicycling is the confirmed stoop which has already declared itself in many wheelmen, a result so common in the less strongly built bicyclists of the continent as to have found its way into classification as the "kyphosis bicyclistarum." The dorsal curvature posteriorly, which used to be rare in boys under fourteen years of age, is, now that the bicycle is so largely used, very frequently met with, particularly among those young bicyclists whose spinal column is developing more rapidly than the ligaments and muscles, and in whose case, therefore, the equilibrium between those parts is more or less disturbed. Were it merely an unsightly deformity, the stoop in question ought to be combated in every way; but confirmed dorsal curvature posteriorly has consequences of its own quite mischievous enough to call for immediate counteraction. The displacement, embarrassed functional activity, and arrested or diseased development of the organs which kyphosis inevitably induces, are all too serious to warrant the slightest neglect in remedying them. Exercise of a kind to accustom the spinal column to an action directly antagonistic to the inclination forward of the bicyclist's attitude is what is needed. The use of the Indian clubs or such similar means of incurvating the spine anteriorly, throwing out the chest and maintaining the head erect, should be practised with that object. All the undoubted advantages of bicycling may thus be retained, without that cultivation of the stoop which tends to take a cubit from the stature of its inveterate exponents, and to impose a hunchbacked development on what it would then be a figure of speech to call the rising generation.—*Lancet.*

Ophthalmic Solutions and their Ready Sterilization.—Dr. Sydney Stephenson has recently presented before the London Ophthalmological Society a set of new eye-drop flasks devised by Dr. Stroschein, of Würzburg. Sterilization by boiling is facilitated by the use of these flasks, in respect of solutions of atropine, etc., that are in daily and hourly use. The flasks are four in number, and vary in color with the different solutions they are to contain. A white bottle is prepared for cocaine, a black one for atropine, a blue for homatropine, and a red one for physostigmine. In addition, the name of the drug is deeply etched on the flask. The cost of a set of these flasks is, in London, less than three dollars. The peculiarity of the flasks consists in their being made of thin glass, so that they do not break under the application of a small flame. A pipette accompanies each flask, the india-rubber cap of which is removed during the application of heat. A wire gauze on a little tripod goes with the set. This supports the flask with its pipette while the solution is being boiled for three minutes over a small spirit-lamp. Solutions that are in constant use should be thus treated at intervals of a few days. To obviate the tendency of these boilings to concentrate the solution, it is Dr. Stephenson's practice to add a few minims of distilled water before each boiling.—*New York Medical Journal.*

Pan-American Medical Congress. Notice to Intending Contributors.—The regulation of the Congress providing that abstracts of papers shall be in the hands of the Secretary-General on or before July 10th, was framed to give the Literary Bureau ample time in which to make the necessary translations, and publish the four editions of the book before the assembling of the Congress. The request that abstracts be sent in even before the date indicated has been so generally complied with, and the work is so far advanced, that the Literary Bureau finds

itself in position to accept abstracts during the remainder of July. To insure careful translation and publication, however, they should be sent in at the earliest possible date. It is suggested that abstracts be made as full as possible within the six-hundred-word limit.—Charles A. L. Reed, Secretary-General, 311 Elm Street, Cincinnati.

The Section on Diseases of Children of the Pan-American Medical Congress, under the presidency of Dr. John M. Keating, is rapidly completing its programme. The titles of a large number of papers have been received and the attendance promises to be large. Many prominent men whose names have become identified with this department of medicine will be present. Physicians interested in the study of the diseases peculiar to children are cordially invited to attend these meetings. Those desiring to contribute papers should send the titles at once to the secretary, Dr. Floyd M. Crandall, 113 West Ninety-fifth Street, New York.

Mr. Luther Holden.—The distinguished author of "Holden's Osteology" and of "Manual of Dissections" recently passed through the country on his way home after a tour of the world. Mr. Holden is seventy-eight years of age; he is, however, as clear in mind and body as when he wrote the books which have been read with genuine pleasure by successive generations of medical students.

The World's Fair.—The various surgical exhibits at the Chicago Exhibition are to be found in the Department of Liberal Arts, in the gallery of the Manufacturers' Building. By exception, however, and for some unexplained reason, the principal part of the German surgical exhibit is in the northeast gallery of the Electricity Building. The exhibit of surgical splints is near the centre of the United States surgical exhibit.

Under Laws of most States the physician is exempted from jury duty, on the ground that his occupation is affected with a public use. In defiance of this principle, more than one city has attempted to exact a license-fee from the physician. Norfolk, Va., furnishes the latest instance of this demagoguery.

The New Buildings of the Chicago Medical College.—The laboratory of the new buildings for the Northwestern University Medical School, which has been in process of construction for a year, is now completed. It is a handsome building, one hundred and ten feet square, constructed of stone, pressed brick, and terra-cotta. It contains large, finely lighted and appointed laboratories of physiology, physiological chemistry, pathology, histology, bacteriology, chemistry, pharmacy, botany, anatomy, and operative surgery, besides lecture-rooms and museums. Some of the novel features of the building are the distribution of live steam through it, by which much cooking can be done without gas; the distribution of compressed air to the lecture-rooms, and an ice-machine for the preservation of anatomical material, by means of which the ice-box can be kept at any desired temperature and kept dry as well. Besides the Laboratory building, another college structure, the South Side Dispensary, is rising and will be completed in the autumn. In it will be additional lecture-rooms, and accommodations for the Dispensary. The building will be fifty-five by one hundred feet in surface area, and four stories in height. Mercy Hospital is being enlarged and doubled in capacity. Its four hundred beds, the one hundred and fifty at St. Luke's Hospital, and forty at Wesley, will give the college nearly six hundred beds from which to obtain subjects for bedside clinics. The new college buildings are on Dearborn Street, between Twenty-fourth and Twenty-fifth Streets.

The Case of a British Army Surgeon.—The recently settled case of Surgeon Briggs, of the British army, demonstrates therein a condition of affairs which could not exist under the vilest political spoilsman of the United States. Dr. Briggs attended the wife of an English nobleman who had been forcibly subjected to sexual pervert outrages by her husband, while resident in India. The wife appealed to the London Divorce Court and summoned Dr. Briggs from Calcutta as a witness. She obtained her divorce amid universal execration at the vileness of her husband, through whose social influence Dr. Briggs was dishonorably discharged from his position in the army. The Duke of Cambridge, commander-in-chief of the British army, superciliously resented all attempts of Dr. Briggs to secure justice. Appeal to the House of Commons resulted in complete reinstatement of Dr. Briggs, with the declaration that his discharge had been illegal and of non-effect. With such revelations in the British army medical service, with the recent showing that the Marquis of Salisbury and a couple of dukes are able to set sanitary ordinances at defiance by social influence, British criticism on the American spoils system is in decidedly bad taste. The mote in the American eye stands no comparison with this British beam.—*Medical Standard.*

The Pan-American Medical Congress Excursion to Rome.—It has been definitely determined that the Pan-American Medical Congress excursion to the Eleventh International Medical Congress will sail on the steamship Werra, from New York, September 9th, the day following the adjournment of the Congress at Washington, and will arrive at Genoa September 20th, four days before the opening of the Rome meeting. Round trip steamer tickets may be procured for $142.50 for inside rooms, and $150 and upward for outside rooms. Tickets are good for members of the Congress and their families, and may be used at option of holder to return on any steamer of the line from Genoa, or on Saturday steamers from Bremen, or Sunday steamers from Southampton, during the months of October, November, and December. Physicians desiring to avail themselves of this exceptionally low rate should at once become members of the Pan-American Medical Congress by sending the registration fee ($10) to the Treasurer, Dr. A. M. Owen, Evansville, Ind., and informing the Secretary-General, Dr. Charles A. L. Reed, Cincinnati, of their intention to join the excursion. Passage should be secured without delay, as the trip, involving, as it will, a stop at the Azores and Gibraltar and a sixty hours' sail along the picturesque coasts of Spain, France, and Italy, promises to be very popular. Many prominent European guests of the Pan-American Congress will return on this occasion. The time allowed will afford American physicians an opportunity to not only attend the International Congress and visit Rome, but to extend their journey to the famous sanatoria of South France and the Riviera.

The State of Pennsylvania at Last has a medical law like that of the State of New York. In order to make it thoroughly efficient, the Legislature was obliged to create a supervisory board, corresponding to our Board of Regents, but which is there called the Medical Council. The details of the new law are not at hand at the present writing, but this much we know, there are three boards of examiners, corresponding to the so-called schools of medicine. The examinations are written, and are exactly alike, except in the matter of therapeutics. It was only by yielding to the homœopathic practitioners in the matter of having a separate board that Pennsylvania at last achieved this reform.—*Post-Graduate.*

To Regulate the Character of Patent Medicines.—The following bill was introduced into the New York State Legislature. It failed to pass, but it is an effort in the right direction, and we print it in the hope that our readers may exercise their influence with the next set of legislators in order to secure some supervision of patent medicines.

Section 1. In addition to the powers now conferred by law upon the State Board of Health, said Board is hereby empowered, and it shall be its duty, upon receiving a fee therefor of $50, to cause an examination and analysis to be made by a practical chemist of any drug, medicine, or mixture of drugs, herbs, or medicines, commonly known as patent or proprietary medicines, and shall ascertain and determine whether the use of the same may not endanger the public health; and it shall not be lawful for any person or persons, or corporation, to sell or offer for sale any such drug, medicine, or mixture not prescribed by a regular physician, unless the same shall have been so examined and approved and certified.

Professor Von Esmarch has done 20,000 important operations. He is now seventy years of age, and if he lives ten years more he will stop working and write his memoirs.

The Kentucky School of Medicine has joined the four-year class.

A Congress of Nonogenarians at Paris.—The editorial staff of *La Science médicale* has undertaken to convene, for scientific purposes, a considerable number of aged persons. No distinction as to nationality will be made in regard to old people who are provided with documents proving that they have passed the age of ninety years. Expenses of travelling and lodging at good hotels are to be defrayed by the medical committee in charge of the affair, and the well-being of the delegates will be cared for during their stay at the congress. Three gold medals will be awarded, one to the oldest, one to the strongest, and one to the most intellectual. Although there are supposed to be not fewer than two hundred centenarians in France, the presence of a few only of them may be expected; by far the greatest number of them reside in the departments that skirt the Pyrenees. It is supposed that the congress will have for its president Dr. De Boissy, who practised medicine at Havre for seventy years. He was born in April, 1793. Dr. De Boissy is still vigorous, and not long since read a scientific paper before a public meeting. The convention will be called to order on July 25th at the Palais des Arts libéraux.—*New York Medical Journal.*

The Cincinnati College of Medicine and Surgery.—The chair of the Principles and Practice of Medicine in this school has been tendered to Dr. J. C. Culbertson, the retiring editor of the *Journal of the American Medical Association.* Dr. Culbertson has returned to the editorial chair of the *Lancet and Clinic*, after an absence of two years at Chicago.

A Medical Bishop.—A district of southeastern Africa, called Lebombo, has been apportioned to become a new diocese, and the Rev. William E. Smyth, M.D., has been appointed by the Anglican Church authorities to the bishopric.

Odi Persicos.—On June 24th, Goolam Kader, a notorious Arabian quack oculist, was held for trial in Special Sessions on a charge, made by the Medical Society of the County of New York, of practising medicine without a license; bail being fixed at $500. A few days previously he had opened an office and inserted glowing advertisements in a number of newspapers, including several published in French, German, and Italian. One of these attracted the attention of Dr. Ferdinand C. Valentine, an accomplished linguist, who, as the editor of *Medical Abstracts*, is in constant receipt of all the foreign medical journals; and he at once recognized the name as that of a quack who, on account of his outrageous practices, had been prosecuted in Genoa, Brussels, Cologne, Berlin, and many other Continental cities. Dr. Valentine found from his reading that his favorite operation was that for cataract, and that in consequence of his so-called "cures" hundreds of cases of total blindness had resulted. He at once reported the fact of the man's establishing himself in New York to the County Medical Society, and the career of this dangerous charlatan here was quickly cut short. The other American cities will now have to be on the lookout for him.—*Boston Medical and Surgical Journal.*

Reviews and Notices of Books.

The Cardinal Symptoms of Urinary Disease. Their Diagnostic Significance and Treatment. By E. Hurry Fenwick, F.R.C.S. Eng., Surgeon to the London Hospital, Surgeon to St. Peter's Hospital for Stone and other Urinary Diseases. 8vo, pp. 349. London: J. & A. Churchill. 1893.

This volume is the outcome of a very careful clinical study of two thousand cases of urinary diseases of different varieties, most of which were seen by the author in consultation or hospital practice. The thorough and patient examination of salient symptoms, their significant diagnostic points, and the practical indications for treatment, are presented in such an intelligible and tangible form that they cannot fail to interest and instruct everyone who devotes his time to the edification, not to say enjoyment, of the volume. To anyone who has been accustomed to rely upon the older methods of investigation before the employment of vesical illumination, new and enticing fields of study are constantly presented in the skilfully recorded cases, and the practical application of cardinal principles that is evolved. The divisions of the general subject are comprised in the discussion of hæmaturia, frequent micturition, vesical irritability, and the direct and reflex neuroses of urinary diseases, concluding with an interesting and instructive chapter on abnormal urination. This is a natural clinical division of symptoms which pertain to a large class of pathological conditions which are, for the most part, of a perplexing character to the superficial

observer. Under hæmaturia, which is the subject most exhaustively treated, a careful examination of its different sources in the urethra, prostate, bladder, ureter, and kidney is practically demonstrated. Thus, in the estimation of each and all of the pathological processes associated with bloody urine, we are led to consider the different traumatisms, inflammatory conditions induced by vesical, urethral, and renal calculi, mechanical irritations, and morbid and benign growths of the urinary tract. The proper understanding of the varied causes of these troubles prepares the reader for the practical application of principles of treatment which, as may be anticipated, are judiciously and intelligently carried out. The study of frequent micturition is invested with a clinical interest which is also in keeping with the general purpose of the work, and is a fitting preparation for the appreciation of the excellent exposé of obstructive disease in its relation to vesical irritability, and the lucid explanations of the significance of pain and reflex neuroses. The chromo-lithographic plates are well made and typically illustrative of salient pathological conditions. Altogether it is a classic of its kind, and will well repay careful perusal and patient study.

Handbook of Pathological Anatomy and Histology. With an Introductory Section on Post-mortem Examinations and the Method of Preserving and Examining Diseased Tissues. By Francis Delafield, M.D., LL.D., Professor of the Practice of Medicine, College of Physicians and Surgeons, Columbia College, New York, and T. Mitchell Prudden, M.D., Professor of Pathology and Director of the Laboratories of Histology, Pathology, and Bacteriology, College of Physicians and Surgeons, Columbia College, New York. Illustrated by 300 Wood-engravings, printed in black and colors. Fourth revised and enlarged edition. New York: William Wood & Co. 1892.

This admirable treatise is so well known that praise is superfluous. A comparison of the present with former editions will convince the reader that not only have many new drawings been added, but the text has been thoroughly revised and amplified. The work is illustrated by a large number of wood-engravings, many of them printed in colors, of unusual excellence of workmanship, clean cut and distinct. The chapters on the respiratory system, alimentary canal, and bones are particularly noticeable in this respect, although many of the drawings illustrating tumors are also very superior. The section on infectious diseases, again, is rich in colored drawings representing the various kinds of pathogenic micro-organisms.

In the introductory section to the chapter on tumors, we note that the authors maintain a conservative attitude with regard to the recent parasitic theory of the origin of carcinoma.

The work is, we venture to say, one of the finest specimens of the bookmaker's art to be found in medical literature at the present day, and apart from this it will, by reason of its intrinsic value and of the undisputed authority of its authors, continue to maintain its prominent position as a worthy exponent of American progress in pathology.

The Electro-therapeutics of Gynecology. By Augustin H. Goelet, M.D., Fellow of the New York Academy of Medicine and of the New York Obstetrical Society, Vice-president of the American Electro-therapeutic Association, Editor of the "Archives of Gynecology, Obstetrics, and Pædiatrics," etc. Two vols., pp. 194 and 203. Detroit: George S. Davis. 1892.

These little volumes include a complete résumé of the subject of electro-therapeutics as applied to diseases of women. Volume I., consisting of five chapters, is devoted entirely to electro-physics and electro-physiology, and for that reason will be less interesting to the general reader than Vol. II. The criticism to be urged against the chapter on apparatus applies to nearly all the recent monographs on this subject—too many and too complicated appliances are mentioned. The general practitioner (for whom the book is ostensibly written) has neither the money nor the inclination to provide himself with such expensive instruments. If, as one would infer, these are indispensable to the proper employment of electricity, most men would be deterred from using it.

The second part of the book deals with electro-therapeutics, which one would infer may be profitably applied to every pelvic trouble, from amenorrhœa to pyo-salpinx and hæmatocele. The author's extreme views on this subject are familiar to specialists, few of whom follow him as far as he is inclined to go. Nevertheless, there are many valuable hints to be found in this volume, which bears the marks not only of scientific enthusiasm, but of wide experience.

No candid observer questions the value of electricity as a palliative measure in the treatment of many pelvic disorders, and it is manifest that those are best entitled to set forth its claims who have applied it most carefully and patiently.

We find much to commend in Dr. Goelet's book, but would suggest that condensation would render it both more readable and more useful to the general practitioner.

Diseases of the Skin. Their Description, Pathology, Diagnosis, and Treatment, with Special Reference to the Skin Eruptions of Children. By H. Radcliffe Crocker, M.D. (London), Fellow of the Royal College of Physicians of London, Physician for Diseases of the Skin in University College Hospital, etc. Second Edition, Revised and Enlarged, with 92 woodcuts. Philadelphia: P. Blakiston, Son & Co. 1893.

Many valuable additions to the original text and the introduction of wholly new chapters, for the most part devoted to subjects which are either themselves new or made necessary to look upon in a new light by modern investigation and advance, render this second a decided improvement upon the first edition. As now presented to students and those engaged in general or special practice, it may safely be claimed to be the most complete work in the English language. In order that the student may most benefit from his study, especial attention has been paid to the arrangement of subjects, and a page of instructions has been added showing how to make the best use of the work.

From his long connection with the East London Hospital for Children, the author has been enabled to give particular attention to eruptions as they occur in childhood. This is a feature of the work which is usually much neglected in general text-books, and its value is the greater from the known practical experience which the writer has had in this field. Among the new articles are noticeable those on Morvan's and Darier's diseases, adenoma sebaceum, epidemic exfoliative dermatitis, seborrhoic dermatitis; which is the same condition of dermatitis under its various forms, to which Unna gave the name eczema seborrhoicum, erythema induratum, parakeratosis variegata, etc. An appendix containing an analysis of twelve thousand cases, information concerning natural mineral waters, formulæ, varnishes, plasters, mercurial hypodermic injections, and other useful knowledge is added. There are 987 pages including the index, and as the publishers have tacked on some thirty odd pages of advertising matter, it makes quite a heavy volume. The print and paper are good.

The Anatomy of the Peritoneum. By Franklin Dexter, M.D., New York. Published by D. Appleton & Co., New York.

This little book shows the development of the peritoneum, which offers the student of anatomy suggestions that cannot be found in the text-books. The illustrations are diagrammatic, some of which are colored.

Smoking Compartments for Ladies are now provided on all Russian railway trains.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 18, 1893.

D. B. ST. JOHN ROOSA, M.D., PRESIDENT, IN THE CHAIR.

The Organization and Equipment of the Division of Disinfection of the New York Health Department and the Method of Work.—Dr. Hermann M. Biggs read the paper. The object was to furnish to the medical profession of the city more detailed information in regard to the methods of this department of the Health Board, and to solicit their assistance in the work which it had to accomplish in limiting the spread of contagious diseases, etc. Until September, 1892, the work of disinfection was included in the duties of the Department of Contagious Diseases. Then it was transferred, making a department which included bacteriology, pathology, and disinfection, Dr. Biggs being placed at the head of this department. Under the present regulations the city was divided into sixteen districts, and to each district was assigned a medical sanitary inspector. Whenever a case of contagious disease was reported to the Health Department this inspector was sent to the house, and it was under his instructions that the methods of disinfection, etc., were carried out. The directions in the work assigned to the sanitary inspector were essentially as follows: Every case of contagious disease must be visited on the day of the report. School cards were to be at once sent to principals to exclude children from the schools who resided on the same floor, or all children in the house, if a dwelling or boarding house. Scholars excluded were not again received until notice was sent of the termination of the disease and disinfection of the premises Under certain circumstances isolation in the house was permitted. A circular on contagious diseases was distributed among the families in the house. The inspector had to revisit the patient if isolated in the house at least every four days and report to the chief. If, however, the house was occupied by but one family, the inspector visited the patient only at the request of the family physician. At the termination of the illness the central office was notified and disinfection was made.

Organization of the Department of Pathology and Bacteriology. — The headquarters of this department were at 44 Bleecker Street, and the disinfection department at the foot of Sixteenth Street. Thirty men were employed, there being a chief inspector, an inspector of bacteriology, etc. The paper gave a detailed description of building, which contained the cremation furnace, the disinfection apparatus, etc., at the foot of Sixteenth Street. The disinfection chamber measured inside seven feet in length, six feet in height, and six feet in width. The articles to be disinfected were put into this chamber from one room and taken out in another entirely shut off from the first. The employees on the two sides did not intermix, and were distinguished by brown and white suits. Heat and steam were employed for disinfection in this chamber. There were also provisions for disinfection of certain articles by solutions of corrosive sublimate and carbolic acid. The department in Bleecker Street was the place where bacteriological investigations had been made. This work had consisted chiefly in examinations for suspected cases of cholera and typhus fever, and in distinguishing between true diphtheria and pseudo-diphtheria. A large number of cases reported as diphtheria were found on bacteriological investigation to be pseudo-diphtheria. This being true of many cases in which the diagnosis of true diphtheria had been made by the attending physician, the inspector and perhaps others. This work was under the charge of Dr. Dunham. The department has also made a bacteriological analysis of the water-supply and of milk, and of the germicidal value of disinfecting processes.

There were about twenty supply depots throughout the city for disinfectants. Wagons delivered the disinfectants at these depots, and it was there that the disinfectors for the district obtained their supply. A sample valise was shown which contained the articles used by the disinfector in the prosecution of his work, as pans, bichloride tablets, sulphur, overalls, and all articles required in the work. In using sulphur in a room, three pounds were burnt for each thousand cubic feet of air-space; the room was made as tight as possible, and the air saturated with moisture during the disinfection process. The most difficult point was in disinfecting the upholstery, and owners were advised to have their furniture reupholstered. Bedcovers, etc., were disinfected at the foot of Sixteenth Street. The amount of work done was only faintly suggested by the fact that over sixteen thousand pieces had been received and disinfected at the station during the first quarter of this year. Ambulances carrying patients to the Willard Parker Hospital were disinfected after each trip. The disinfection of carpets, like that of upholstered furniture, had caused Dr. Biggs considerable thought. They ought to be rolled up and kept from exposure as soon as the nature of the disease was known.

The President read a brief communication from Dr. Janeway, expressing belief in the wisdom of establishing a bureau with such a complete equipment as Dr. Biggs had detailed, and advising all to co operate with the Health Board in combatting preventable diseases.

A Chance for Philanthropic Money-making.—Dr. A. Jacobi wished to again call attention, as he had done two or three times before, to the need of a place where the well children could be taken when a case of contagious disease developed in a family. Again, there ought, as he had said before, to be many Willard Parker Hospitals, and especially one where well-to-do-people could be taken who might get diphtheria, scarlet fever, etc., while stopping at hotels. Since the city could not keep a hospital specially for those well able to pay for service, he thought it would be not only an act of philanthropy, but a paying enterprise for some doctors to establish a private hospital of that nature—to be, however, under the general supervision of the Health Department. He knew of hotels in which diphtheria broke out in certain rooms year after year, simply because the proprietors did not take such steps as would destroy the germs before new tenants were put into them.

Dr. Joseph D. Bryant, to whom credit was given for establishing the department of which Dr. Biggs was the head, was called upon, and said that such a department had been the dream of his existence during the six years he had been connected with the Health Department. The contrast with the state of things in 1886 was very great. At that time the place for disinfection had been aptly compared to a smoke-house. In the fall of 1887 Mayor Hewitt willingly gave the department $3,600, with a view of establishing a suitable disinfecting apparatus, and under the direction of Dr. Prudden and Dr. Biggs the present apparatus was put up, certain improvements having been made since. Then the ability to isolate cases of contagious disease had been wonderfully increased by new pavilions, etc., built in the past few years.

He said the reference of Dr. Jacobi to sick guests in hotels applied with equal force to private houses. There was no escape from such cases except to remove them to the hospitals, where patients coming from tenement-houses were also received. The next great step in advance would be a hospital where persons of means could be received and have at their own expense all the advantages which could be obtained in their own homes, such as the attendance of a private physician, nurses, etc. It would be in a general way under control of the Health Department.

The value of the bacteriological work done by the department could hardly be better illustrated than by the fact that over fifty per cent. of the cases admitted to the hospital as cases of diphtheria were shown by bacteriological examination to be a simple form of membranous

sore throat. Besides proving a protection to the sick and well, such knowledge promoted the interests of the city by lowering the percentage of a serious disease. Dr. Bryant closed by urging the earnest co-operation of the profession with this department.

Dr. Brannan said the importance of having separate hospitals or pavilions for the several forms of contagious disease had also received attention in England. It was necessary, in order to avoid the possibility of a patient suffering from one disease, say from measles, acquiring a more serious one, as scarlet fever. Might not the same accident occur by using one ambulance for transportation, in spite of the custom of the department to disinfect it after each trip?

Credit to Bacteriology.—Dr. T. Mitchell Prudden said that when we looked back a decade in bacteriology we saw work now accomplished in the prevention of disease which had hardly been dreamed of ten years or more ago. Another thing was the promise, or at least the hope, of curing patients with contagious diseases by such means as experiments based on bacteriological research might discover. Unfortunately, a good many people—and it seemed a good many doctors, too—were standing in the way of work in this line, instead of helping it along. The Board of Health deserved much credit, as it not only was not a stumbling-block, but was even taking the lead. It should have the warm co-operation of the medical profession.

Flies, Meat, and Cholera.—Dr. G. M. Sternberg said with regard to diphtheria that he had not so much faith in sulphur fumigation, since the germs in the diphtheritic membrane on clothes, carpets, etc., were difficult to destroy.

As to cholera, it had been demonstrated that the dejecta of flies might contain living cholera spirilla, and he had had some experience which led him to think flies might have been the means of spreading the disease by alighting upon articles of food, especially meat. In 1867 he was in an isolated camp in Kansas. Some troops from St. Louis were posted on the opposite side of the river and below. The water-supply was quite distinct. Cholera, which existed among the troops from St. Louis, first appeared in the butcher of the other camp. Doctor Sternberg and the nurses who attended many cases afterward escaped, and none but the servant-girl in the hospital contracted the disease, and she handled the meat.

Dr. Beverley Robinson impressed the need of a hospital where strangers could go with contagious disease, by reciting a case to which he had been called at a hotel during the naval parade. The man, an Englishman of note, had to be taken to the Willard Parker Hospital among cases from all parts of the city.

Contagious Ophthalmia.—The President took advantage of the opportunity, and called the attention of the physicians present connected with the Board of Health to the fact that there was also need of a hospital for those suffering from contagious ophthalmia, for it should be remembered that the blind were a burden upon the State, while those dead from scarlet fever and other contagious diseases were not.

Dr. Biggs closed, and said that of the twelve cases of cholera in the city last fall, seven were in butchers or their families, and only one in a person not connected with a food trade, making it not improbable flies had carried the poison.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, May 25, 1893.

H. J. Boldt, M.D., Chairman.

Symphyseotomy. — Dr. J. Clifton Edgar presented an Austrian on whom he had performed symphyseotomy March 24th. The conjugate was estimated at three and a half inches, and it was thought the head might pass by aid of axis-traction forceps. These were tried, but without success. The parents objected to any cutting operation, preferring destruction of the child, but Dr. Edgar performed symphyseotomy and extracted a living child, he cut from above downward and from before backward. Podalic version was performed, and some difficulty was experienced as the head came through. There was still slight motion at the symphysis, but it did not interfere with walking.

The Symphysis will Care for Itself.—Dr. Howard A. Kelly, of Baltimore, thought too much anxiety had existed as to union at the symphysis following symphyseotomy. He wished to put on record a case which had a bearing on this point and because it was the second one in America so far as he knew. The woman came to Johns Hopkins Hospital after an exceedingly difficult labor, during which there had been spontaneous separation at the symphysis, which was followed by abscess and sequestra from the pubis. There was absolutely no joint, yet after repair of an enormous vesico-vaginal fistula and other treatment demanded by her lesions, repair at the symphysis began to take place and they expected to get union and a useful joint. Her gait was improving and becoming less waddling.

Dr. A. F. Currier related a case briefly which served to show that nature probably often allowed separation of the symphysis sufficiently to allow the passage of a child which the attendant thought would call for interference.

Fibroid of the Uterus; Mummified Fœtus.—Dr. H. T. Hanks presented a fibroid of the uterus which he had removed by abdominal hysterectomy, and on clearing out the bottom of the pelvis was surprised to find some bones, evidently the remains of a tubal abortion. Inquiry of the husband brought out the fact that four years before the patient had had symptoms plainly pointing to tubal abortion, which had not been diagnosticated. She was recovering.

Operation in Tubal Pregnancy Without Evidence of Tumor.—Dr. Hanks presented another specimen removed from a lately married woman who was suffering from symptoms which at first were thought to point to uterine abortion. Since on the third day after the first attack of pain and hemorrhage there was another attack and no ovum escaped, he suspected tubal pregnancy, and Dr. Lusk agreed with him as to the propriety of laparotomy, although no tumor could be distinctly made out. The operation established the correctness of the diagnosis based on the subjective symptoms, for the ovum was found in the tube. The patient did well.

Small Uterine Fibroid Unexpectedly Found to be Pedunculated.—Dr. Hanks also presented this specimen. The patient had been given ergot, etc., for relief of hemorrhage from a fibroid supposed to be single. She returned unimproved, and then examination showed apparently a multilocular tumor in the utero-vesical space, but none of those who had examined the patient had had the least suspicion that it was a pedunculated fibroid, which it proved to be, the pedicle being very small. Dr. Hanks thought the case taught us that it was best to open the abdomen when uterine fibroids were producing symptoms, and do, according to the circumstances, enucleation, removal of the appendages, or hysterectomy—any one of the three procedures being safe at present in the hands of good operators.

Diseased Uterine Appendages.—Dr. Ralph Waldo presented the enlarged and thickened tubes and ovaries removed from a patient that afternoon, and expressed the opinion that the tubes were the seat of malignant tumor, though the chairman believed there were only chronic inflammatory changes. The patient had suffered three years and had borne no children, although she desired them—evidence to him that the bagginess at the sides of the uterus involved the appendages.

Uterine Fibroid.—Dr. Waldo also presented a uterus removed for a fibroid which involved its entire body and which contained a cyst in its centre.

Hæmatoma of the Vulva.—Dr. Grace Peckham Murray related a case of this condition and exhibited a drawing. The paper also contained a brief survey of the sub-

ject, by which it appeared that obstetricians might attend from two to five thousand confinements without meeting with the accident of hæmatoma of the vulva. The case which she related occurred in a primipara, aged thirty-two, who showed prominence of the peripheral venous system, especially of the lower extremities, and during pregnancy was directed to wear elastic stockings. The labor, at term, had been completed without instruments, although, owing to the fact that the perineum had been unyielding and painful, a little chloroform had been used, and there was a slight rupture—not sufficient to call for suture. A few hours later the nurse noticed that a swelling began to form in the left labia which soon increased to the size of an orange. It was tense and glistening. Dr. Murray saw the patient soon after, and the tumor had already begun to subside and had nearly disappeared by the fourth day. Many clots were removed from the vagina and vulva. The treatment had been expectant and antiseptic—frequent douching with bichloride solution. The elastic stockings were taken off soon after the tumor had formed, and it was thought that they might have had some causative influence by producing pelvic stasis. There had been no varicosity of the veins about the vulva beforehand. In treatment, some advocated operative, some non-operative treatment. The author thought one would be guided by the circumstances of the case. In adopting the expectant plan in this instance she had been influenced by experience with a case of large pelvic hæmatocele, which had rapidly disappeared. Much care should be taken to keep the parts aseptic. The mortality in the past seemed to have been about twenty-five per cent. It probably had been greater than it would have been were it not for want of asepsis on the part of midwives and others having charge.

Urinanalysis in Gynecology.—Dr. Howard A. Kelly, of Baltimore, read a paper on this subject. In his opening remarks he said that some present might think he had given too much attention to the subject of albumin in the urine, but it should be remembered that the rank and file of the profession were still alarmed when they found that the urine contained even a small amount of albumin.

In gynecological practice the kidneys were more important than any organ outside the pelvis, for if they were much diseased the patient would not be likely to survive an important operation.

The immediate practical import of renal examination was: 1, that we might refuse to operate where there was advanced renal lesion, thus lessening the mortality list; 2, in less advanced kidney disease one might by suitable diet, bathing, massage, and purgatives, avoidance of alcoholics, and watchfulness throughout convalescence, save life; he had not observed bad effects from the hypodermic use of morphine in these cases when it was called for; 3, we would be led to operate earlier if the condition were one which was liable, if allowed to go on, to lead to renal complication; 4, we would use chloroform instead of ether, although he had not observed ill effects from ether in these cases; 5, one would be more likely to use drainage, as drainage acted as an extra emunctory; 6, one would avoid subjecting these patients to prolonged examination or operation under ether, or any unnecessary delay.

For reliability examinations of catheterized specimens of urine alone should be made. Or if a voided specimen showed albumin, the examination should not be considered complete until the catheterized specimen had also been examined. A slight amount of albumin, though persistent, did not necessarily signify any disease of the kidneys. Nor was the presence of albumin in considerable amount significant in the absence of casts. Albumin was often significant of mild cystic inflammation, as evidenced by a few pus cells; the presence of a few hyaline or small granular casts was not important in the absence of vascular changes and other symptoms indicative of renal disease. Transient glycosuria was occasionally found and was without significance. Diabetes mellitus contraindicated abdominal operations. Albumin found in patients with large tumors often disappeared entirely after operation. Albumin was often found in the urine after pelvic and abdominal operations when it did not exist before. When present before the operation it was apt to show increased quantity after, due apparently to mild cystitis excited by concentrated urine passed after operations. Diminished secretion following operation, even as low as 290 c.c. per diem for three or four days was not unusual, and need cause no alarm as to suppression of urine or of the possibility of having ligated one of the ureters. That was a very practical point, one which had relieved him of a great deal of anxiety. Persistent diminished urinary secretion after operation associated with elevation of the temperature, the pulse becoming more and more rapid, was not a sign of nephritis, but of sepsis. In such cases fatty degeneration of the kidneys would usually be found post mortem. He was sure that, not knowing this fact, operators had often attributed death to kidney disease when peritonitis was the true cause. The same statement held good with reference to fatty heart; after numerous experiments Heller's test for albumin had been returned to in daily work. Trichloracetic acid had been given up on account of its over-sensitiveness.

It was important in all hospital work to have systematic urinary analysis, and to keep records in a chart similar to the one shown. Where repeated analysis was resorted to, the results were noted in a large ward book and the history put into shape for statistical use. Such records had been made in Johns Hopkins in all cases the past four years, so that their statistical value was great. The conclusions just cited were based on exact records of two hundred cases of abdominal operations and on perhaps six hundred more where the records were not as complete.

Dr. Noble, of Philadelphia, read a brief paper in continuation of the discussion. It confirmed Dr. Kelly's observations in almost every particular. In his early career he had had three deaths from suppression of urine following operation, a fact which had impressed him with the important relationship between the kidneys and a successful issue of an operation. Albumin was often present before operation—in his experience in about ten per cent. of all cases. It was not often significant. The urine in the female patient should be drawn by catheter, and if not, the external genitals should be washed before that intended for examination was voided. The pressure of a tumor might cause albumin. Tube casts were not always significant, but when present should receive special consideration. The presence of chronic contracted kidneys was apt to give the surgeon serious trouble, and in such cases albumin was often absent or only occasionally present, and tube casts might be absent. He had operated upon two women whose urine had been examined by a pathologist for over two weeks, with negative results, yet in both patients there were contracted kidneys, and they died. If repeated examinations showed a small amount of albumin, tube casts, and urine of low specific gravity, the surgeon should be on his guard. The prognosis after operation was better in women having fairly large tumors, especially ovarian cysts. In them generally the operation was easy, quick, without sepsis, and after removal of the tumor, and relief from pressure, the patient was apt to secrete even more urine than before. Dr. Noble had also found the urine considerably decreased after operations, and believed it to be a matter of universal observation. The quantity had been about ten ounces the first day, to nineteen on the fourth day.

The Pathological View.—Dr. W. H. Porter thought the significance of a urinary analysis could be best understood by bearing in mind that a healthy individual living in a physiological way would secrete about a given quantity of urine with certain ingredients. Any marked deviation would indicate a pathological condition, and he had long believed that so-called Bright's disease was, in nearly all instances, secondary to trouble elsewhere, more especially to disturbance in the nutritive system, which

caused increased and abnormal work to be done by the kidneys. The nutrition of the kidneys was interfered with, and increased work being added the renal cells underwent retrograde changes, and instead of getting the normal constituents of the urine one found by-products—products indicative of incomplete proteid oxidation. He would say that albumin, when it came from the kidneys, was always indicative of pathological changes of renal protoplasm, and while he did not mean that it indicated a fatal issue, yet it should be considered evidence that there was some abnormal process beyond the kidneys which should be corrected before a more serious state ensued. The more marked degenerative changes were apt to be preceded by the secretion of a small quantity of urine, of high specific gravity, high color, super-acidity, and one should always seek to bring the urine around to its normal quantity and constituents before resortion to an important operation. He had repeatedly seen patients operated upon when secreting scanty urine of high specific gravity, high color, though without albumin or casts, taken to the autopsy table within twenty-four or forty-eight hours, or showing albumin and casts and serious renal symptoms after the operation. His explanation was that the etherization, which implied absence of oxidation, had caused a retrograde change along the whole line of tissue metamorphosis, and granular change of the kidneys, and perhaps of other organs. After relating a case, Dr. Porter again impressed the necessity for bringing the nutritive and secretory organs into line before operating.

The Diagnosis of Masturbation, Uterine Fibroids, etc., by Urinanalysis.—Dr. Charles Heitzman said that as he was known to be a fighter he could not be expected to agree with all that the previous speakers had said. He was surprised to hear a paper on urinanalysis in gynecology which only dealt with albumin and corpuscles in the urine, scarcely mentioning casts, and seeking only to diagnose the condition of the kidneys themselves. One should distinguish between essential albuminuria and albuminuria of kidney disease. With albumin, pus corpuscles, and especially kidney epithelium one could be sure there was a certain amount of so-called Bright's disease. His Philadelphia friend had operated on two cases in which there was atrophied kidney and the patients had died. Was it possible that our microscopic and physical signs could not enable us to make a diagnosis in such cases? Of course the patient would die!

A few casts and albumin were not a contraindication to operating, it was true. Then there were some cases in which but one kidney was diseased. There was a form of kidney disease with little albumin which was a serious form, because it led to cirrhosis of the organ; such cases did not withstand ether well.

But while the kidneys were themselves very important organs, and it was desirable to know their condition as far as it could be determined by examination of the urine, yet urinanalysis should reveal more of the patient's condition. It should and would reveal the constitutional state. Not only that, but by urinanalysis he had diagnosed such conditions as endometritis, masturbation, tumors of the uterus, sarcoma of the kidney, etc. Among the amusing cases related by the speaker was that of a woman whom a friend out of the city was about to marry, but grew suspicious of her virtue, and by a little diplomacy procured through the chambermaid a specimen of her urine, which Dr. Heitzman examined, and diagnosing endometritis, advised him not to marry her. Another related to a specimen of urine from a woman whose husband had lost one arm in the Confederate army. In advising Dr. Kelly to extend his schedule in urinanalysis, Dr. Heitzman expressed fear that Baltimore and Philadelphia were too far away from New York.

The Chairman asked Dr. Kelly a few questions, among them whether the frequency of nephritis in cases of malignant disease might not be explained by the constitutional condition producing the nephritis.

Dr. Kelly made some closing remarks. He had been struck by Dr. Heitzman's wonderful power to make a diagnosis in the cases related, but what had puzzled him most was how he had been able by examining the woman's urine to tell that her husband had only one arm.

A vote of thanks was tendered the gentlemen who had come from distant cities and given the section the benefit of their experience.

OUR LONDON LETTER.

(From our Special Correspondent.)

DEBATE IN PARLIAMENT ON ARMY SURGEONS—THEIR GRIEVANCES—"COMBATANTS'" PREJUDICES—THE GYNECOLOGICAL SOCIETY—DISPLACEMENTS, VAGINAL, UTERINE, AND OVARIAN—OPERATIVE TREATMENT—THE LATE DR. ALEXANDER HENRY.

London, July 1, 1893.

Parliament had before it the subject of Army Surgeons last Tuesday, and the medical profession is generally indignant at the tone adopted by some members of the House of Commons. Mr. Hanbury, who led the attack, ridiculed "hankering after military titles," and said we should next have the chaplains demanding military rank and commanding their congregations at church. A fine specimen that of the logic of those professing to despise "non-combatants" who are continually exposed to all the dangers of the service. He wanted to know why the recommendations of the Camperdown committee had not been carried out, and appeared utterly unconscious that the army surgeons would also be glad to know why. Mr. Bartley, too, complained of the cost of the "non-effective service," and thought the War Office must now put its foot down and refuse all concessions to the medical department. Mr. Morton said the medical department cost half a million a year and contained too many ornaments who drew high salaries and did very little work. He was good enough to add that the title of Doctor was higher than Field-marshal, but he did not say if the latter was ornamental and carried good salary with little work! It is true that the opinions of these members will not carry any weight, but their expression in the House was felt to be insulting to hard-working officers. Dr. Farquharson said the pay of army surgeons was not excessive. To get good men a fair price must be paid. The additional year in India which has been imposed on medical officers is a terrible strain. Out of twenty-five sent to India, seventeen died or were invalided, and of the eight survivors two had to be removed to the hills. The military officers can get frequent leave to go to the hills, and can always arrange their work so as to keep out of the heat of the day, while the doctor is at everyone's beck and call at all hours of the day and night. Mr. Jeffreys also spoke sympathetically and urged that in time of war the country needed the best surgeons, and rank ought to be given them, for they were poorly paid compared with what they could earn in civil life. Colonel Lockwood testified to the stress of the doctors' work in India, and said it was so great that the term ought to be shortened. General Goldsworthy spoke in the same sense, and said doctors ought to have extra leave to recruit on the hills. Sir G. Chesney, however, surpassed himself in the ignorance he displayed on the subject on which his prejudices induced him to speak. He declared that army surgeons were in no sense military persons, except as being under the mutiny act, pretty much like nurses. He added they were never required to take part in active operations, and the combatant branch felt degraded by the concessions already made to non-combatants. No doubt Sir G. Chesney may fancy himself degraded as an engineer at any justice done to a doctor, but he does injustice to himself by such absurd statements, just as he did when he pretended that the chief duty of

the senior medical officer in the field was to make poultices. He would sing a different song if he were wounded.

It is some satisfaction to report that the War Minister was much more reasonable, admitted that the medical officers were much more exposed to climatic dangers than the combatants, and intimated that he would do his best to meet every substantial grievance that was brought under his notice.

The British Gynecological Society has put itself much *en evidence* lately. Dr. Leith Napier read a paper giving his experience and a critical review of the operative treatment of vaginal, uterine, and ovarian displacements. His paper excluded minor proceedings and referred only to those in which important operations were proper. Vaginal displacements were usually associated with deficiency of perineum and might give rise to cystocele or rectocele or both. For rectocele, the operation required was mostly colpo-perineorrhaphy. For cystocele he has modified the plan of Stoltz, removing a circular piece of mucous membrane and passing a purse-string suture around so as to obliterate the raw surface. This proceeding should be combined with that of Hegar, Martin, or Doléris when both rectocele and cystocele are present.

For uterine displacements various plans have been tried. Anteflexions should be treated by bougies if stenosis were present, and by biconical amputation of cervix when that is hypertrophied, circular amputation being apt to cause undue contraction. Retroflexion and prolapse can be met with vaginal or abdominal operation. The author recommended the latter. The extra-peritoneal procedures he discarded and of the intra- he preferred direct fixation and adopted a modification of Ferrier's plan and described the operation in detail. The results were satisfactory in thirteen or fourteen cases, and fifteen cases of successful parturition following ventro-fixation had been recorded or were known to him. For ovarian displacements suspending the uterus was advised. To remove the ovary, if displaced but healthy, he regarded as a surgical crime.

In the discussion on this paper Dr. Phillips thought the mode of ventro-fixation described was the best, but would like to hear the results, as he considered the patient ought to remain well for three years before being pronounced cured. Dr. Heywood Smith said he had done Stoltz's operation for the first time in England, and Professor Stoltz was himself present. Dr. Routh said enough stress had not been laid on the hypertrophy of the vaginal mucous membrane in many cases of prolapse, and many cases were cured by attention to this condition. Mr. Spanton said many cases of prolapse were due to the weight of the uterus, but others to laxity of the vaginal walls. For a heavy uterus with weak ligaments he approved of ventro-fixation, but if the vaginal walls were lax they should first be dealt with. He had had no fatality in vaginal operations. He thought one fatal case in fourteen condemned any operation for prolapse. As to the ovary, he thought if healthy it would not prolapse, but to remove a prolapsed ovary, even if healthy, entailed less risk than ventro-fixation of the uterus. Dr. Schacht thought the risks of the operation of ventro-fixation were only those of complications, the operation itself was no more risky than removing a simple cyst of the ovary. Dr. Travers gave details of the fatal case mentioned in the paper. Death came on with pyæmic symptoms after the patient had done well for a time. At the autopsy no mischief was found in the abdomen and the uterus was well fixed. In his reply, Dr. Napier referred to Badouin's work on hysteropexy, in which three hundred cases were tabulated with only one or two deaths. He preferred the operation with its risks to leaving the cases unrelieved and a reproach to gynecologists.

Dr. Alexander Henry died on the 24th ult. He was a very learned, modest, retiring, and taciturn man. He was also a notable linguist. For thirty-four years he laid his remarkable gifts and prodigious industry on the altar of the British Medical Association. All this time he was content to occupy the position of sub-editor of the Association's journal, although his learning and sagacity probably surpassed that of all the rest of the staff combined. But his modesty and shyness were not calculated to push him forward, and while colleagues appeared to make wealth from less work he toiled quietly on and died comparatively poor.

MEDICAL ASPECTS OF THE WORLD'S FAIR.

(From Our Special Correspondent.)

The Hospital Exhibit properly commences with the Emergency Hospital of the Medical Bureau, which, however, was not intended as an exhibit. Here may be seen modern appliances, used in a modern way, by modern men. Dr. John E. Owens, Professor of Surgery in the Northwestern University Medical School, is the Medical Director. There are four Attending Surgeons, two Resident Surgeons, and a Superintendent of Ambulance Service. All are mature men, specially qualified for their positions by previous experience. One attending surgeon, generally two, and sometimes three, and one resident surgeon, are constantly on duty in the hospital. There is a druggist, a superintendent of nurses, ten trained nurses, and four orderlies.

The hospital is situated in the southeast corner of the Service Building, with an entrance from the courtyard of that building, and near the Sixty-second Street entrance to the grounds. It contains thirty-nine beds, besides many rattan cots, which serve in most cases more satisfactorily than the regular beds.

The beds are of the latest pattern for hospital service. In one of the male wards is a cage-bed for delirious patients. It consists of a cage of woven wire placed over an ordinary iron cot-bed and securely fastened to it. The wire is of such strength that it cannot be bent by the patient; and the arch of the cage is so low that the patient can neither sit up nor do himself harm.

The operating-room has a tile floor and is furnished with glass tables, instrument-cases, and appliance for aseptic work, many of the instruments and fittings being supplied by Truax, Greene & Co. In an adjoining room such dressings are done as might endanger the purity of this room.

The ambulance department is in the hands of Dr. Gentles, who has one sergeant, fifteen ambulance men, and five drivers. The ambulance men are physicians, medical students, or others that have had previous ambulance service. There are one hundred and fifty ambulance call-boxes in the various buildings and about the grounds. The guard reports all cases of emergency and remains at the box to guide the ambulance, as in case of fire or police call. One hundred and fifty stretchers are distributed about the various buildings. There are four ambulances, two furnished by the Abbot-Downing Co., and two by Studebaker Bros. Each ambulance is furnished with a folding-stretcher, padded bed, blankets, a large canvas bag containing the following: Gauze, sponges, basin, Esmarch's bandage, water, roller bandages, oil for burns, carbolized vaseline, Esmarch's tourniquet, antiseptic tablets, medicine glass, safety-pins, chloroform, nitrite of amyl pearls, aromatic spirits of ammonia, dressing splints, scissors, and a hypodermic case with solution of digitalin, ether, nitroglycerine, morphia, atropia, and apomorphia. One ambulance is stationed at the hospital, one near the Terminal Railway Station, one near the Stock Pavilion, and one near the east end of the Midway Plaisance, near which is a Tollet portable hospital tent which relieves the pressure on the Emergency Hospital.

The nurses are under the charge of Miss M. R. Brown, a graduate of St. Luke's Training School, of Chicago. The ten nurses are from the various hospitals and training schools in this country and Europe. Each nurse is on duty eight hours and off duty sixteen hours, and serves for one month.

There are three sanitary inspectors, whose duty it is to daily inspect every nook and corner of the grounds, and report upon the condition of the same.

The amount of work done by this hospital staff may be learned from the following record. In the "Construction Period," August, 1891, to May 1, 1893, there were:

New cases, medical	2,555
New cases, surgical	3,364
Readmitted, medical	2,738
Readmitted, surgical	3,196
Making a total of	11,853

Of these only 32 are known to have died. In addition to this, 5,370 candidates for Columbian Guards were examined.

During the "Exposition Period," May 1st, to July 1st, there have been:

	May.	June.
New cases, medical	988	1,137
New cases, surgical	489	498
Readmitted, medical	474	533
Readmitted, surgical	670	798
	2,621	2,966

	May.	June.
Number of males	2,509	2,577
Number of females	112	389
In-patients, male	104	106
In-patients, female	35	237
Ambulance calls	315	406
Deaths	4	7
Daily average of cases	$84\frac{54}{100}$	$98\frac{86}{100}$
Guards examined	1,072	293

By "In-patients" are meant those that are for any reason put in bed. None are kept over night. Such as cannot walk away are removed in carriages or by ambulance to their homes or other of the city hospitals, generally to St. Luke's. No meals are served in the hospital for either patients or staff, but in the diet kitchen the nurses prepare soups, teas, and refreshing and stimulating delicacies.

The Homœopathic Headquarters and Hospital is a neat building back, or west of, the Woman's Building. It has recently been completed and may be said to be under the special patronage of President Higginbotham. Some indeed have doubted if the regular profession would have control of the Emergency Hospital had Mr. Higginbotham been in control from the beginning. The building is two stories, with offices, reception rooms, operating-room, and drug exhibit on the main floor; on the second floor are the rooms for patients and nurses. Twelve medical gentlemen, who were chiefly responsible for the building of the headquarters and hospital, make up the attending staff; their positions, however, are chiefly honorary, and their duty seems mainly to consist in having their names inscribed on a tablet on the wall at the entrance. The real work of the hospital is done by Dr. M. R. Baker, House Surgeon, and Dr. Lincoln S. Brown, House Physician.

There are two trained nurses constantly in attendance. At the time of my visit there were two male and two female patients in the hospital. The exhibit of drugs, bags, and cabinets, supplied by the manufacturers, and of instruments and supplies for the operating room from a like source, is very complete and interesting. There is provision for the care of twenty patients; but few find their way there since no ambulance is attached and patients are only taken there by the regular ambulances when they specially request it.

The Woman Physician and Training Schools for the nurses in Illinois have their exhibit in a special building somewhat to the south of that last mentioned.

In the building there is a model operating-room with all appliances; a model diet-kitchen fully equipped for hospital necessities; a model office and reception-room; a section of a child's ward; a section of a woman's ward; and a private room for all patients. In the latter every comfort and convenience will be found, and care will be given to any woman or children who may desire to apply for medical services, or who may be brought to the hospital. All three schools of medicine are represented in the attending physicians: a resident physician of each school being appointed for daily service. Volunteer physicians from each school of medicine are also in attendance for varying periods during the continuance of the Fair. A head-nurse also is constantly in the building, and every training school in the State will be represented at some time during the six months through one or more of their graduates, who will serve likewise for varying periods as circumstances may require.

The Visiting-nurse Association, which is one of the finest and most philanthropical enterprises in the city, and one of the results of the perfection to which the service of trained nurses has been brought, will also have a representation in this hospital building, and the attendant will explain to all those desiring it their system of work among the poor of the city.

The exhibit of instruments and operating-room supplies, as well as many of the other furnishings, are supplied by the manufacturers. Special attention should be called to Reeves's spinal head-rest—for beds. It is simple, easily arranged, adjustable to any angle, and composed entirely of metal. There is an interesting exhibit of the uniforms of nurses of the various schools in the State.

On the second floor of the Woman's Building will be found the British Nursing Section, containing an exhibit of nurses' costumes of Great Britain and her colonies, with china, glass, infant clothing, hygienic clothing, health corsets, bandages, splints, and beds. There is a trunk for the use of the private nurse that is worthy of the highest commendation.

In the Educational Section of the same building, on the main floor, will be found the exhibit of the New York and Brooklyn Training Schools, containing much that has already been mentioned as part of a nurses' exhibit, the exhibit of nurses' uniforms of the different schools, dressing baskets and bags, and a miniature model hospital ward is very complete.

Just to the southwest of the Woman's Building will be found the Children's Building. Here the Fitch Crèche and Training School for Nursery Maids makes a very practical exhibit in the daily care of ninety children of the visitors to the Fair. Ten nurses are in constant attendance. For twenty-five cents any child between the ages of four weeks and six years can be checked in the morning, and will be fed, cared for, and clothed, if necessary, and delivered on presentation of the check in the evening. It is an experience well worth the price, to fumble a brass check in one's pocket, and know that it represents a hot, tired, and crying infant. The rooms of the nursery contain model bassinettes and cribs, swings, and all manner of nursery furniture. In the centre of the room for the younger children is the "Pound," consisting of a movable fence just high enough to keep the little toddlers within bounds. Near the window is another convenient contrivance, consisting of a padded bottom, or floor piece, about three by five feet, and about two feet above this an oblong wooden frame, the two being connected with stout cord netting, and the whole swinging from a framework. Such a swing basket makes a safe and comfortable home for children and toys.

The Medical Section of the Government Exhibit, in charge of Captain Louis A. La Garde, Assistant Surgeon, will be found principally in the Army Hospital, which is an eighteen-bed structure, built in accordance with the plans and specifications furnished by the Surgeon-General of the United States Army. The plan is one of the recognized ones for a Post Hospital, and in the arrangement of the ward, dispensary, storeroom, offices, etc., it differs but little from a permanent Hospital Army Post.

The ward is not fitted up for patients, however, as it is not intended to treat patients there. The space in the ward is to be devoted (1) to the display of two hospital beds to show the pattern of bunk and the bedding in use in army hospitals; (2) models to show the evolution in hospital construction in the medical department of the

army; (3) models of hospital steam vessels and hospital cars; (4) a number of wet and dry preparations illustrating pathological lesions of various kinds; (5) about three hundred bromide enlargements and transparencies, illustrating the various histological and pathological tissues of the body; (6) a series of eighty consecutive sections of human embryos, illustrating the form and structure of osseous tissues; (7) ten series of consecutive sections of human embryos, illustrating the anatomy of various portions of the body; (8) a collection of microscopes illustrating the evolution of the instrument; (9) a collection of deformed leaden bullets, gathered from cases during the War of the Rebellion; (10) a collection of specimens showing bony lesions of gunshot injuries from the same source; (11) a collection of specimens showing the difference in destructive effects upon bones between the leaden projectile of the 0.45 calibre Springfield rifle, and the German silver nantle projectile of the 0.30 calibre experimental rifle.

The dispensary contains a full outfit of drugs, dressings, etc., and the store-room contains supplies for one hundred men for one year. The post surgeon's office contains a collection of medical books and periodicals as per Standard Supply-table of the Medical Department.

Two of the rooms upstairs are used as office and reception-room, and the space in the other rooms is devoted to the use of a Clinical Laboratory.

In this department is shown a number of thermostats in operation, a collection of such cultures as particularly interest the general practitioner, the method of preparing media of various kinds, methods of staining bacteria in and out of tissues, the drying of blood on cover slips, and the staining of the same by the Biordi-Erlich method, to show the difference between anæmias and leukæmias. There is also shown methods of hardening tissues and the cutting of section by the microtome, as well as the more common methods of staining and mounting sections for the examinations under the microscope. For the supervision of this department the services of Dr. W. M. Gray, of the Army Medical Museum, and Dr. Meade Bolton, of the Johns Hopkins Hospital have been secured.

In two framed hospital tents near the hospital are exhibited models showing the evolution in the transportation of the sick and wounded in time of war.

There is exhibited, adjoining the post hospital, a field hospital of twenty-four beds under the charge of First Lieutenant G. D. Deshon, Assistant Surgeon. One of the chief features in this display is a contingent of the Hospital Corps from Fort Riley, illustrating the ambulance service, litter drills, and methods of rendering first aid to the wounded, etc

Although the exhibits of the Medical Department of the Army will be of special interest to medical officers in general, no medical man should visit the grounds without spending as much time as possible studying this department.

HIGH FEES AND LOW FEES.

To the Editor of the Medical Record.

Sir: I see that in your issue of June 24th you refer to the high fees of the doctors in the "Mackay case." I have been thinking for some time of discussing the subject in the newspapers, but your editorial suggests it might be better, perhaps, that it be first considered in a medical journal. It is of interest both to the medical profession and the public. I shall be as brief as possible.

A clothier can only give a man so much for making a coat because he can only sell the coat for so much. A farmer can only give a laborer so much per foot for the ditch dug because the land is only worth so much to him for cultivation. So in these and similar cases there is necessarily a fixed limit to the value of the work done. In medicine and in law there are at least two limits, to wit: The value of the work done and the ability to pay. But the value of the service and the ability to pay have no real connection the one with the other. The poor man's life and health are as dear to him as the rich man's, so the value of the work done is the same. We adopted a tariff of fees from necessity. As most people are poor, the tariff is low. There were no millionaires when it was made. If the ability to pay was the only guide, the schedule would be a long one. If we charge the poor man $2 for a visit, the millionaire should be charged $100. But in almost all transactions the first question to be considered before settlement is the value of services performed. Unfortunately, men seem to lose sight of the value of medical services except in extraordinary cases, such as the saving of life by a surgical operation. Yet there is, or can be, no enjoyment of life without health; hence its inestimable value. Lawyers get their fees secured before they begin work. This is impossible to the doctor, for obvious reasons. The lawyer's fees are also far higher than the doctor's, though he does less work ordinarily. Juries should be very careful how they set aside the doctor's fees. A physician does more charity in one week than a lawyer in a year. The public owes the former much, the latter nothing.

The fees of Mackay's doctors were $5,000 and $7,500; they are considered enormous by some people, and yet lawyers get $10,000, $20,000, and $30,000 fees when less than life is involved. As a class the latter are not as well educated as the former. Were Mr. Mackay shipwrecked and he called upon a good swimmer to save him, and he did it, would $10,000 be too much pay, though it took the rescuer only ten minutes to do the work? We think not. "A man will give all that he hath for his life." It is impossible often to express in money the value of medical services; hence it was once the custom, on the part of men of wealth especially, to give the doctor what is known as an "honorarium," something beyond the fee charged, as an expression of the patient's higher obligation. This was a beautiful custom which has fallen, in the Southern States, into sad decay. There may be a mere mercenary service in medicine, or a high honorable devotion to duty and humanity that loses sight of all pecuniary reward; its motive-power is pure love. Sometimes the doctor's work is heroic. Like a mother's love, we can't find its value. Every man dies a debtor to his mother, and thousands die debtors to their doctors, though the "fee" is paid. Furthermore, the value of the physician's work cannot be estimated, like that of the mechanic. The doctor's knowledge is cumulative. A man with five years' experience may make as good a plough or locomotive as one with twenty years' experience. He only requires a certain amount of mechanical skill of a certain sort. But a doctor with twenty years' experience brings an immense mass of information got from hundreds and thousands of cases. He pours out upon this one case all his careful observations derived from all his cases of a like character, together with the knowledge he has got from books, indeed all his mental wealth. Neither can he disassociate this one disease from the healthful action of the entire system.

No account is taken by the public of the painful sympathy and dreadful anxiety suffered by the doctor in the practice of his art. There is no such strain in mechanical work. He suffers with his patient. He is often miserable on this account. The patient is in his dreams as well as in his waking thoughts. He is often an old and dear friend, a man or woman invaluable in the family and in the community. The doctor's reputation is also at stake. To him all hearts turn in anxious solicitude. It is often intensely painful. I knew an excellent doctor once to flee from this anxiety; he gave up the case rather than endure it. Sometimes the physician has to endure the distress of want of confidence in the patient's friends. The heaviest sorrow borne by the Great Physician was the want of appreciation of his followers. Another mortifying thing in a doctor's life is the reluctance of men to pay their bills, though abundantly able to do so; it must be itemized. Some keep account of your visits, and rebates are asked for, low as the fees are. The love of money in some men seems to

kill out all gratitude, as I showed in my "Forty Years a Doctor." I do not think I am writing from a doctor's stand-point. When I was eighteen years of age I saw that money could not discharge a less obligation than those of a sick man to a kind and faithful doctor. When I left the Academy I said to the Principal, and I was perfectly sincere, as I handed him my father's check for my tuition, "Sir, this is a small expression of my obligation for your valuable services to me." I remember he seemed much surprised.

The public need instructing on this point. How few physicians, after thirty or forty years of hard work, get rich. The great multitude die poor. This is a proof that the fees are not high. The man who does get rich pays a high price for it; he has little rest day or night, and no Sabbath-day to calm his tired and troubled spirit. Few doctors make their sons physicians; they would shield them from a life of toil and hardships. In the South few are able from their practice alone to give their children first-class educations. W. W. PARKER, M.D.

RICHMOND, VA.

New Instruments.

IMPROVED METHOD FOR RELIEF OF SYMBLEPHARON.

BY CHARLES S. RODMAN, M.D.,

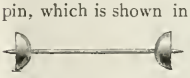
WATERBURY, CONN.

ADHESION of the eyelid to the globe is considered to be the inevitable sequel of severe conjunctival ulceration as occasioned by burns from lime and the stronger mineral acids. It is the lower lid usually that is involved. Quoting from one of the most recent and complete of ophthalmic treatises, "Nothing can prevent the formation of attachments in case the burn is deep, as the resulting ulcer slowly granulates and contracts" (Noyes, p. 266). After ultimate contraction is reached the deformity, if of any great degree, is rarely cured. Many expedients have been proposed, *e.g.*, shields of lead, glass shells, plastic operations, as those of Arlt and Knapp, as well as the transplantation of mucous membrane. Whatever success may have been sometimes attained by skilful operators, it is safe to say that no method has hitherto been made known so simple and effective as to commend itself for general adoption.

Within the past year it has been my misfortune to see several cases of symblepharon, more at least than often tax the patience, if not the skill and mechanical ingenuity of one not connected with large ophthalmic dispensaries; of these, two were treated as often recommended, by passing a gold wire through the base of the connecting tissue, the ends being drawn out of the conjunctival sac, with the intention of forming a lined channel and afterward dissecting the lid from the globe. No great success was attained in this way; in common language the wire worked out, new tissue developed beneath it, while absorption occurred above, making the ultimate effect less than desired. In another case characterized by adhesion of the temporal half of the lower lid and much narrowing of the palpebral opening, a pointed gold wire was pushed from within the lid beneath the attachment, emerging through the integument nearly half an inch from the external canthus. The point was cut off, the wire bent into a ring, and the ends soldered. This ring was worn many weeks with ultimate result much as in the cases previously cited. In all, the deformity was of long standing, and the patients were gratified with a slight improvement.

A few months ago a symblepharon formed almost under my observation. Freshly made mortar was thrown into a man's eye by a fellow-laborer. He came to me, first, a few days after the injury, was under treatment at the Waterbury Hospital until able to work, perhaps a month, then disappeared, and about three months later applied for relief. At this time more than half of the right lower lid was adherent to the globe, new tissue encroaching upon the cornea nearly to the pupillary centre. After dissecting these recent attachments from the globe, I apprehended their reproduction from the extent of the deformity and the small size of the eye with limited amount of healthy conjunctiva to draw upon in covering the corneal wound. Having at hand no convenient rabbit, or individual with superfluous oral or vaginal mucous membrane, a modification of the method attempted in the cases first mentioned occurred to me, which has proved easy and satisfactory.

Guided by Georgen & Hahn, opticians, I obtained from a maker of diamond settings a double-pointed gold pin, which is shown in the cut. It is of 18 carat gold, a



little more than half an inch long, of the calibre used in solitaire settings for the ears, and, like these ornaments, provided with saucer shaped nuts, a thread being cut near each end for three sixteenths of an inch. The smooth central portion is three-quarters of an inch long; the ends are needle-pointed. Having taken off the nuts, the pin is grasped with a strong carrier and pushed from within the lid until the point emerges through the integument below the outer canthus. It is drawn out with forceps, then taken with the carrier and again pushed from within the lid when the other point appears under the inferior punctum lacrymale. Finally, the nuts are put on and turned, slightly compressing the lid, the shaft of the pin lying in and gently pressing against the fornix.

The photograph, taken one month after the pin was inserted, shows this little device *in situ*. It is worn without discomfort or irritation. It cannot work out; adhesions do not occur above the central portion, which is posterior to the lid. A simpler form may suffice, but as made for me it is very convenient and can be used repeatedly. By any one to whom a trial of the method which I have found successful may commend itself, it is obtainable of Georgen & Hahn, 26 East Twenty-third Street, New York.

The Diagnostic Value of Subclavicular Palpation.—Dr. Hottenier calls attention to the value, from a diagnostic point of view, of bimanual palpation of the upper part of the chest. A congestive process limited to the apex may not be distinguishable at its commencement by percussion and auscultation. In such a case Dr. Hottenier recommends the following manœuvre: While one hand is applied over the subclavicular region and the other is maintained over the corresponding scapula, the to-and-fro respiratory movements are followed by the two hands and a moderate degree of pressure is exercised by the pulp of the fingers in front during inspiration. Should no pain be thus elicited, no appreciable lesion of that apex exists. Should the patient, on the contrary, complain of pain, it is a proof that congestion is present.—*Lancet.*

The Pliny Cure for Inebriety.—Dr. Robertson says, in the *Pacific Medical Journal*, "I will match Keeley's secret as regards remedial value and scientific acumen with one I recently found in the 1601 edition of Philemon Holland's translation of Pliny: "For to avoid drunkenesse, take the lungs of an hog, be it bore or sow, it matters not, in like manner of a kid, and rost it; whosoever eateth thereof fasting shall not be drunk that day how liberally soever he take his drinke."

The Esteem of One's Fellows.—In the course of the Croonian Lecture, delivered recently by Virchow, he says: "Who of us is not in need of friendly encouragement in the changing events of life? True happiness is not based on the appreciation of others, but on the consciousness of one's own honest labor. How otherwise should we hold our ground in the midst of the turmoil of the day? How should we preserve the hope of progress and of final victory against the attacks of opponents and the insults which are spared to no one who comes before the public? He who during a long and busy life is exposed to public opinion certainly learns to bear unjust criticism with equanimity; but this comes only through the confidence that our cause is the best, and that some day it must triumph. Such is our hope in our wrestlings for progress in science and art; such is our hope in our struggles for civil and religious liberty, and in this hope we gradually become hardened against malicious attacks. It is a kind of immunization which, I acknowledge, has also great drawbacks, for this hardening toward unjust attacks leads very easily to a similar indifference toward just attacks, and, owing to the tendency to contradiction rooted in the nature of human thought, it finally leads also to indifference to praise and recognition. One withdraws again and again into one's self, discontented with the world and with one's self also; but who can so completely retire within himself that the consciousness of the insufficiency of human thought, and that the criticisms of opponents are justified, cannot break through the crust of even the most hardened self-consciousness? Happy is he who has courage enough to keep up or regain his connections with other men, and to take part in the common work. Thrice happy he who does not lack in this work the flattering commendation of esteemed colleagues."

Inversion of the Uterus in a Woman of Seventy-eight.—Dr. Schauta records the following case: The patient, seventy-eight years of age, had noticed for more than a year that a tumor protruded from her vulva. At first it was small in size and disappeared during the night, later she had to replace it herself, and she had suffered from pains in the back and abdomen, and from a red vaginal discharge. There had also been some difficulty in micturition. She had had one child when twenty years old, and the menopause had occurred when she was forty-eight. The vulvar tumor was found to consist of a completely inverted uterus with a fibroid attached to it. The openings of the Fallopian tubes were clearly seen. The myoma was removed in the hope that then a pessary and tampons might keep the uterus in position; but these means failing, the uterus also was removed. The causes of the inversion, according to the author, were the presence of the myoma in utero, the fact that the woman had to stand for many hours daily, chronic constipation, and the atrophic state of the uterus and the inflammatory infiltration of its walls.—*Archiv für Gynaekologie.*

The Practice of Medicine is Easy in Connecticut.—The Secretary of the State Board of Health of Connecticut, in reply to an inquiry from an applicant, writes:

"Sir: Anybody can practise medicine in Connecticut. You do not need to register; you do not need a medical diploma; you do not need to know the difference between opium and peppermint—you do not, indeed, need to know anything. You can simply come and live here and begin to practise. The laws of Connecticut will sustain you in collecting your fees for professional services, if you render any which you choose to call such. But if you undertake to carry me or my trunk to the depot for pay, you must get a license. If you peddle matches or peanuts, you must get a license. If you collect the swill from your neighbors, to feed your pigs, you must get a license. If you want to empty your cesspool, you must get a license. But you can practise medicine in Connecticut *without a license.*"

Proper Pride.—Ghys, the tramp who enjoys the distinction of having imported typhus fever into Paris, was recently condemned to a fortnight's imprisonment—not for having accomplished this insanitary feat, but for having mistaken somebody else's property for his own. The following dialogue between the accused and the judge is curious reading: Prisoner: "Je venais de Lille. J'étais très malade, j'avais besoin d'argent pour me soigner." Judge: "Quelle maladie aviez-vous?" Prisoner (proudly): "Le typhus! C'est moi qui l'ai apporté au Dépôt à Paris." To what lengths will the rage for distinction lead?—*Lancet.*

The Forms of Diabetes.—Dr. George Harley gives the following classification of diabetes: 1. Hepatic diabetes—including the gouty variety. 2. Cerebral diabetes—including all cases of saccharine urine arising from nerve derangements. 3. Pancreatic diabetes—the most deadly form of the disease. 4. Hereditary diabetes—a form by no means uncommon, and one, too, where both brothers and sisters may labor under the disease without either their maternal or paternal parent having been affected by diabetes, though more distant members of the family may have suffered from it. 5. Food diabetes—including all forms of saccharine urine arising from the ingestion of unwholesome substances. In the matter of treatment, besides diet and opium or codeine, Dr. Harley recommends croton chloral, strychnine, phosphoric acid for thirst, and an absolute prohibition of alcohol.

Meat Eating and Bad Temper.—One deplorable result of excessive meat eating is the ill-temper which is said to be a chronic complaint in England. "In no country," declares Mrs. Ernest Hart in the *Hospital*, "is home rendered so unhappy and life made so miserable by the ill-temper of those who are obliged to live together as in England. If we compare domestic life and manners in England with those of other countries where meat does not form such an integral article of diet, a notable improvement will be remarked. In less meat-eating France urbanity is the rule of the home; in fish- and rice-eating Japan harsh words are unknown, and an exquisite politeness to one another prevails even among the children who play together in the streets. In Japan I never heard rude, angry words spoken by any but Englishmen. I am strongly of opinion that the ill-temper of the English is caused in a great measure by a too abundant meat dietary, combined with a sedentary life. The half-oxidized products of albumin circulating in the blood produce both mental and moral disturbances. Brain-workers should live sparingly if they would work well and live long. Their force is required for mental exertion, and should not be expended on the task of digestion, for 'they should remember that the digestion of heavy meals involves a great expenditure of nerve-force.' The healthful thing to do is to lead an active and unselfish life, on a moderate diet, sufficient to maintain strength and not increase weight."

THE STRONGLY COUNTER-IRRITANT EFFECTS OF THE USUAL MASTOID OPERATION.[1]

By ALBERT H. BUCK, M.D.,

NEW YORK.

CLINICAL PROFESSOR OF THE DISEASES OF THE EAR, COLLEGE OF PHYSICIANS AND SURGEONS, MEDICAL DEPARTMENT OF COLUMBIA COLLEGE; CONSULTING AURAL SURGEON, NEW YORK EYE AND EAR INFIRMARY, AND THE PRESBYTERIAN HOSPITAL.

THE main object kept before the mind of the surgeon in opening into the mastoid process is the establishment of a free channel between the outer world and the centre of disease, which latter, in most instances, is situated either in some part of the middle ear or in the mastoid bone itself. Through this channel the products of inflammation find a much easier way of escape than by any route that nature may establish through ulcerative action, and through it, besides, the surgeon is able to introduce such remedial or mere cleansing fluids as he may think likely to exert a curative effect. But in certain cases, and they are by no means rare, the good effects of the operation are not confined to the benefits directly attributable to good drainage and thorough cleansing of the parts; the derivative or counter-irritant influence of the operation plays, I believe, a very important part in effecting a cure of these cases, and it is for the purpose of directing attention to this point that I have prepared the present paper.

Setons and issues were looked upon as valuable therapeutic agents even so recently as twenty-five years ago, but nowadays one scarcely ever hears them mentioned. In operating upon the mastoid we may establish an issue on a comparatively large scale. A gaping wound, two or three inches in length, is made in the skin, and a pit large enough to admit the end of the forefinger is excavated in the underlying bone itself. This deep excavation may be left gaping, and afterward, for a time at least, be treated as an open wound. When this course is adopted, we have all the essential conditions of a large issue; and if there be any virtue in the principle of counter-irritation, the beneficial effects that flow from it will be provided in liberal measure to the patient thus operated upon. On the other hand, if the edges of this gaping wound are stitched together in accurate coaptation, only a small outlet for the discharge being left at the lower angle; and then, if, in addition, such dressings are applied that no micro-organisms can by any possibility find an entrance into the wound, our patient will certainly be deprived in large measure, if not wholly, of whatever good effects counter-irritation is competent to supply. In the majority of cases, as I have already intimated, the disease will be cured without the aid of such additional counter-irritation, but in those cases in which the disease of the ear has set up more or less active intracranial inflammation, this counter-irritant power may be sufficient to turn the scale from a fatal to a favorable issue.

While I cannot hope to furnish from my case-book convincing proofs of the correctness of this doctrine, I believe that the histories of the following three cases will go far toward establishing its soundness:

CASE I.—The patient, a vigorous man, about thirty-eight years of age, consulted me in March, 1890, for the relief of a discharge from the left ear, of at least thirty years' standing. Aside from the discharge and some impairment of the hearing, the ear, he said, had given him no trouble until within a few days, when a certain amount of bleeding became associated with the discharge, and had continued since. On examination I found the left external auditory canal filled with a large and very vascular polypoid growth. I removed it with the snare and found that it sprang from what was left of the drum membrane, in the neighborhood of the hammer. I recommended the daiiy use of Angelo's ear-douche, and under this *régime* the ear gave him no further trouble during the subsequent three years.

On April 15th or 16th of the present year, he sat at an open window, with a current of air blowing upon the left side of the head. Soon afterward the ear became painful, and the pain continued to increase steadily until the 18th, when he called upon me to obtain relief. On examination I found that the upper cutaneous wall of the left external auditory canal was markedly prolapsed. There was a scanty, rather thin, pinkish, foul-smelling, discharge in the canal. The body-temperature was 103° F., and the pulse 102. The pain was referred to the deeper parts of the ear, and to the whole left side of the head. There was no tenderness over the mastoid region.

The treatment adopted, and carried out by my associate, Dr. Robert Lewis, was the following: A free, curving incision was made across the cutaneous wall of the canal at the point of greatest prolapse, and through this opening a slightly curved silver cannula was introduced. Through this a stream of a 1 to 4,000 bichloride of mercury solution was forced by air pressure generated through the instrumentality of a rubber foot-bag. This irrigation brought away an appreciable quantity of foul, cheesy material; the stream apparently escaping directly from the middle ear. Three leeches were also applied behind and below the ear, as close as possible to the auricle; and the patient was instructed to have hot flax-seed poultices applied continuously for three hours. Internally, he was given one grain of calomel, to be followed, the next morning early, by a full dose of Rubinat Condal water.

On April 19th the patient was found to have less pain, and the temperature had fallen to 102° F. The probe, passed through the opening in the prolapsed portion of the wall of the canal, encountered everywhere roughened bone. Dr. Lewis therefore attempted, by passing a small-sized Volkmann's spoon (bowl = 3 mm. in diameter) through the artificial opening, to gnaw away so much of the intervening ridge of bone—presumably carious—that the stream of water from his cannula would play directly upon the contents of the antrum. In this he apparently succeeded, for in the subsequent washing he drove out considerable quantities of foul, cheesy material.

During the next two or three days all the local symptoms improved greatly. The discharge almost entirely lost its foul odor, the prolapsed wall of the canal returned to its natural position, the temperature and pulse became nearly normal, and the pain had very decidedly diminished in severity. The appetite, however, did not return, and the patient showed no desire to leave his bed. His tongue also remained heavily coated. The urine had been examined by his regular medical attendant, Dr. Samuel K. Lyon, and found to be normal.

On April 25th the temperature again rose to 103° F., and the patient seemed to have passed into a state of semi-stupor. As the ear had improved so markedly, it was thought that there might be a malarial element underlying the rise in temperature and the mental hebetude.

[1] Read before the American Otological Society, at its meeting in New London, Conn., July 18, 1893.

Accordingly quinine was administered in divided doses until he had taken, during the twenty-four hours, twenty grains. An ice-cap was also kept constantly applied to his head. These measures produced no perceptible effect upon either the temperature or the drowsiness, and at the suggestion of his physician he was given two doses (about four hours apart the one from the other) of the hydro-bromide of hyoscine, $\frac{1}{120}$ grain in each dose. This was on April 26th.

On April 27th the patient was found to be greatly improved in every way. The temperature had fallen to normal. The drowsiness had disappeared, the dusky color of his face had changed to a natural ruddy hue. His eyes were bright. He asked for food. In a word, he seemed at last to be on the high road to getting well.

The visible parts of the ear having shown no signs of inflammatory action for at least three or four days, and apparently not requiring any other treatment than the frequent use of the warm douche with a very weak sublimate solution, the patient was left in the charge of his regular attendant.

As we afterward learned, the improvement noted above lasted only about twenty-four hours. The fever and drowsiness then returned, the right side of the body became paralyzed, and the patient died on the third or fourth day after we had last seen him.

This case is brought forward on account of the indirect testimony which it furnishes of the correctness of the statement that in those cases where the ear disease has already set up a certain amount of inflammation at the base of the brain, it is not sufficient to thoroughly drain and cleanse the original seat of the disease in the ear. Something more potent is required to bring about a subsidence of the deeper-seated inflammation, and this is to be found, I believe, in the counter-irritation furnished by the usual mastoid operation. In direct confirmation of this belief I will give the details of a second case in which the local conditions of disease in the ear were very much the same as those noted in Case I., while the evidences of intracranial disease, at the time of the operation, were more pronounced. In fact, there was already well-marked paralysis on the opposite side of the body, and yet the patient recovered.

Case II.—The patient, a man twenty-two years of age, and of good general health, consulted me at my office, on January 7, 1893, on account of long-standing trouble in the left ear. He gave the following history: There had been a discharge from the left ear since childhood, and on several occasions he had experienced pain in the ear, lasting perhaps for two or three days and then passing off. The last of these attacks had occurred during the previous November and had been of unusual severity. From that time to the present he had experienced a great deal of dizziness, and at times he had felt decidedly chilly, without having, however, a distinct chill. At other times he had felt feverish. The discharge, during this period, had remained unchanged in quantity, but from time to time he had found it streaked with blood. His general health had deteriorated appreciably during this period, and he had lost flesh to the extent of twenty pounds. Quite recently there had developed a new symptom which had given his family some alarm. I refer to the sensation observed on the right side of walking on cushions. His gait, too, had become somewhat unsteady, through his inability to perfectly control the motions of the right leg.

When the patient called at my office, I observed that he dragged the right leg a little, and that he presented the facial aspect of one who was seriously ill. An examination of the ear revealed the existence of a large polypoid mass which nearly filled the left external auditory canal. After it had been removed, it was found that an opening into the tympanic cavity existed in the vicinity of Shrapnell's membrane. A slender probe was introduced, but no exposed bone was encountered. Hyperostosis of the inner half of the external auditory canal concealed a large part of the drum membrane. The odor of the discharge coming through the sinus was very offensive. There was no tenderness or redness at any point in the immediate neighborhood of the ear. Mastoid operation advised.

On January 10th, three days later, I found the patient, at his home in the country, materially worse. There was a moderate elevation of temperature (about 101.5° F.), and his pulse varied from 100 to 110 beats per minute, being at the same time quite weak. He had scarcely any power over the movements of the right leg, and he expressed himself as feeling very ill. Shortly afterward he had a distinct chill.

Ether was administered and the operation of opening into the mastoid antrum was performed in the usual manner. The bone was found to be everywhere of ivory-like consistence, requiring considerable force of the mallet to drive the chisel through it. Volkmann's spoons proved to be of no use until the antrum had actually been reached. They were then used in enlarging the opening into this cavity. By repeated injections of a warm 1 to 4,000 bichloride of mercury solution, and by the frequent employment of the slender middle-ear probe, which was pushed as far as possible in all directions, the cavities of the middle ear were finally cleared of their foul cheesy contents. It was surprising how large a quantity of this material was stowed away in this comparatively small space. A careful exploration was made for the purpose of ascertaining whether, through destructive ulceration, an opening had not been established in the bony tegman tympani. No such opening, however, could be found.

The edges of the wound were left gaping; iodoform gauze dressings were applied; and daily cleansing of the parts constituted the essential feature of the after-treatment. (The patient was under the care of Dr. T. H. Andress, of Sparta, N. J.) About the fifth or sixth day, when it was found that the case was progressing favorably in every respect, the edges of the granulating wound were approximated by means of a silver suture, which had been put in place (ready to be utilized at some later date) at the time of the operation. On February 16th, five weeks after the operation, the patient called to see me at my office. The external wound had entirely healed but there was still a very slight discharge from the external auditory canal. All pain in the ear and head had disappeared, and the right leg had returned to an entirely normal condition. His general health was excellent.

In the following case, thanks to an error which I made in the diagnosis, I am warranted in excluding wholly from consideration the possible effects of drainage and cleansing upon the favorable course pursued by the obscure deeper-lying disease. Absolutely no ear disease whatever was found to exist in this case at the time of the operation, and consequently, in weighing the therapeutic effects of the latter, we are perfectly justified in speaking of it as an issue pure and simple. The history of the case is as follows:

Case III.—The patient, a lady about fifty years of age, and, up to the time of the attack, in good general health, contracted a bad cold in the head early in April, 1892. This was soon followed by tinnitus and pain in the left ear, and impairment of the hearing. The pain resisted the ordinary measures employed for its relief, and gradually increased in severity. It involved the entire left side of the head, but was referred more particularly to the mastoid region. When the patient was seen by Dr. Thomas E. Satterthwaite, about May 1st, he found decided swelling and tenderness of the auricle and neighboring soft parts; the motions of the jaw caused pain in the left ear; the glands on the side of the neck, below the ear, were swollen; and there was a tense swelling on the posterior wall of the pharynx, behind the left tonsil. An incision of this swelling afforded escape to a considerable quantity of creamy pus. The posterior wall of the left external auditory canal was found to be swollen, and an incision in this region also gave vent to a certain amount of pus. From this time onward, for a period of nearly three

weeks, the patient experienced comparatively little pain in the ear or in any part of the head. The hearing on the left side soon returned to a fairly normal condition. Pus, however, continued to escape from the opening in the posterior pharyngeal wall, and the patient steadily grew weaker. The constant escape of pus into the fauces rendered her less and less desirous to take food. In fact, she had to be coaxed a great deal before she could be induced to take the necessary amount of nourishment. It was observed, too, that her mind was beginning to be perceptibly affected, and the pupil of the left eye was noticeably larger than that of the right. The body-temperature did not at any time during her illness rise above 99.5° F. The pulse-rate was about 80, and the pulsations, as might be expected, were feeble. About May 20th she was seen by Dr. Robert Abbe, of this city. He was disposed to refer the source of the pus, which continued to flow abundantly from the opening in the pharyngeal wall, to disease of the sphenoid bone. He advised against operative interference. Shortly after this, the patient again began to complain of pain in the left mastoid region, and it was found that the hearing of the left ear had again become somewhat affected. There was also some redness of the skin behind the left ear, together with slight tenderness on pressure. As these symptoms persisted, I was asked (May 26th) to see the case in consultation with Dr. Satterthwaite, and Dr. Terhune, of Passaic, N. J. I found the patient in a condition of semi-stupor; whether from simple physical weakness or not, I could not determine. Her pulse was 80, and decidedly weak. There seemed to be some redness and swelling of the left mastoid integuments, but as a blister had been applied over the lower part of the process, and some distance below it, two or three days previously, I could not feel sure of the correctness of my observation. The external auditory canal and the membrana tympani were entirely free from any evidence whatsoever of inflammatory action. The spitting-cup, filled with water, was shown to me, and in it, floating as a separate mass, was about a tablespoonful of thick yellow pus. This represented, I was told, the entire quantity that the patient had spat out during the previous twenty-four hours. An examination of the pharynx revealed no points of special interest. The exact spot from which the pus escaped could not be verified by mere ocular inspection.

In the presence of such conflicting evidence—a history pointing strongly to the left ear as the primary seat of all the trouble, and yet, at the time of my examination, an almost entire absence of any recognizable disturbance in that ear—I felt considerable hesitation about putting forward even a diagnosis of probabilities. Nevertheless, from the sequence of pathological events, and especially from the recent return of mastoid pain and tenderness, I felt disposed to believe that there was still, in the substance of the mastoid process, a small remaining centre of osteitis, the purulent products of which were escaping through some opening in the under part of the process, presumably in the vicinity of the digastric fossa, and were seeking an outlet through the unhealed opening made with the knife in the post-pharyngeal abscess. This centre, I assumed, must necessarily be somewhat removed from the mastoid antrum, and from that part of the process which constitutes the posterior wall of the external auditory canal; for otherwise it would have betrayed its existence by redness or swelling of the soft parts of this canal, both of which conditions (as already stated) were absent. I further argued that if, perchance, this diagnosis should prove to be correct, the more direct drainage and ultimate healing of this centre of mastoid inflammation which we might reasonably expect to obtain by an operation, would in all probability cause the post-pharyngeal abscess to heal.

On the following day, May 27th, the operation was performed. A curving incision, about two and a half inches in length, was made through the skin and periosteum, the outer surface of the mastoid bone was freely exposed, and by means of the chisel and mallet and Volkmann's spoons a large part of the bone substance lying external to the antrum was removed. Not a trace of anything like diseased bone was found, either in the main body of the bony prominence or in the direction of its tip, a large part of which was removed with the Volkmann's spoons. There was not even any recognizable congestion of these parts. In a word, the mastoid was found to be in a perfectly healthy condition.

The edges of the wound were left gaping, and simple iodoform gauze dressings were applied. From this time forward the patient, who remained under the care of her regular attendant at first, and then for a brief period under that of my associate, Dr. Robert Lewis, improved steadily although not rapidly. In the course of from four to five weeks the outside wound had healed, the discharge from the post-pharyngeal abscess had ceased, the mental disturbances had disappeared, and she had fully regained her general health and strength.

By way of summing up, let me rehearse briefly the salient distinguishing features of the foregoing three cases. In the first two it is highly probable that the intracranial lesions were very nearly alike in extent and intensity. In the one the original centre of carious bone, with its accumulation of foul *débris*, was effectively cleansed and drained, and yet the intracranial disease pursued its course to a fatal termination without manifesting any but a transient tendency to quiet down under the influence of this drainage and cleansing. It had acquired so great an independent momentum that it no longer needed, for a continuance of its harmful course, the stimulus of the adjacent centre of middle-ear disease. The same remarks, I believe, apply with equal correctness to the second case. Here, too, the original centre of carious bone disease in the middle ear was drained and cleansed, but the intracranial disease, instead of growing worse, underwent a steady and permanent change for the better. To what shall we attribute this favorable change if not to the powerful counter-irritant effect furnished by the presence of an extensive issue in the immediate neighborhood?

Finally, in the third case, the conditions of our problem in therapeutics are rendered peculiarly simple by the entire absence, so far as could be ascertained, of any centre of disease in the middle ear or mastoid bone. In this case, therefore, the establishment of an issue pure and simple is the only therapeutic procedure of which there can be any question. Indisputable, too, is the existence of some deep-seated and serious disease; whether at the base of the brain, or in the sphenoid bone, or where, is just now a matter of no special importance. The patient's full and, on the whole, rather quick recovery completes the series of facts. Do they not warrant the conclusion that counter-irritation, in the form of an extensive issue, effected the cure obtained in this case?

The Results of Coddling.—We know what is the matter with him, and have known it all along. He is very delicate, and the least draught of air will throw him into a chill. He suffers from cold feet and darting pains, and has the most miserable kind of an appetite. He is either greatly depressed or highly elated, and has an abiding conviction that he is soon to be called to render up his accounts. He believes in faith-cure and Christian science, yet he is the constant patron of his family physician, thanks to his faithful wife. Poor woman! She warms his shoes for him every morning, for fear they may be a trifle damp. She gets all his clothing ready, so he may jump into them quickly without too long exposure of the body to the air. She feels of his head for fear it may be too hot, and chafes his feet that the circulation may be good for the day. The poor careworn, anxious wife declares "he is so delicate," and he, the fool, thinks he is. Now what is the diagnosis in this case? She fusses too much! If such men had no one to fuss over them, they would become strong and well within three months. We often write of the nervous hysterical woman; but deliver us from the grunting man spoiled by the mistaken kindness of a devoted wife.—*National Medical Review.*

THE RÔLE OF THE POSTERIOR URETHRA IN CHRONIC URETHRITIS.[1]

By BRANSFORD LEWIS, M.D.,

ST. LOUIS, MO.

LECTURER ON GENITO-URINARY SURGERY AND VENEREAL DISEASES, MISSOURI MEDICAL COLLEGE; CONSULTANT IN GENITO-URINARY SURGERY TO THE ST. MARY'S INFIRMARY, THE CITY HOSPITAL, THE MISSOURI PACIFIC HOSPITAL, THE FEMALE HOSPITAL, THE BAPTIST SANITARIUM, ETC.

The erratic conduct of gonorrhœa is a matter of universal knowledge. It is probably the only feature of that interesting disease upon which there is wide consensus of opinion. Gonorrhœa varies from that simple and benign malady which the sophisticated young man would rather have than a bad cold, to the disease which, through its ultimate effects, undermines health and destroys life; from the three day indisposition to the endless *goutte militaire*.

Without consuming more time on the discussion of this feature of the variation in the length of time required for the cure of a gonorrhœa, let me express the uncertainty of this subject at the present day by quoting the honest and candid words of Dr. George E. Brewer, in his article on "Acute Urethritis," in the recently published "American System of Genito-Urinary Diseases." After giving statistics of cases in which cessation of discharge followed the use, after two weeks, of bichloride irrigations, he adds: "These statistics I believe to be as conscientiously prepared and as accurate as any others gathered in the same manner from the same class of cases suffering from this disease, yet I believe them to be absolutely worthless from a scientific point of view, for even my comparatively limited experience in the treatment of urethral disease has taught me that the simple cessation of discharge by no means indicates a cure of the disease; and I am prepared to say, without the slightest hesitation, that it is my belief that had a careful and thorough examination been made in each instance at the time when I reported the cessation of all discharge, not one case of my three series of cases would fail to show the unmistakable evidences of uncured urethritis, which might, under favoring conditions, again become active and furnish a secretion which would become contagious.

"Regarding the length of time necessary to effect a complete and perfect cure by this or any other method of treatment, I must confess myself wholly unable to present a rule which would be even approximately correct, as in this disease, perhaps more than in any other, success depends upon so many conditions which are intimately associated with the temperament, personal habits, and general health of the patient."

Before the advent of Neisser's gonococcus, and while the discussion as to the virulent or non-virulent nature of gonorrhœa was still on, both sides in this discussion had little difficulty in explaining these widely differing variations in duration and severity of the disease; the non-virulists explained it on the ground that the disease, urethritis, was not bound to any degree of regularity by ties of specificity or uniformity of origin, but was regulated in this respect by many extraneous as well as intrinsic influences, such as the hygienic conditions prevailing, the susceptibility of the patient, his condition of health, etc.; while the virulists held this very variation to be one of the chief marks of distinction between virulent contagious gonorrhœa and non-virulent or simple urethritis, and accounted for it on that score—light cases being looked upon as non-virulent, the others as virulent.

Since the presentation and dissemination of the belief in the gonococcal origin of true gonorrhœa, the non-virulistic school has thinned out to a condition almost of silenced minority; and we, firm supporters of that doctrine, are allowed, without confutation, to complaisantly account for the wide variances alluded to on the score of the presence or absence of the gonococcus—asserting that true gonococcal urethritis does not get well under four or five or six weeks, while those cases which do recover in less time than that are doubtless not due to the gonococcus, but are the product of some of the sixteen kinds of urethral organisms which Legrain[2] has run down and described to us as being eminently capable of inducing different forms and grades of urethritis.

I am a firm believer in Neisser's gonococcus and its noxious possibilities, but I cannot believe that the presence or absence, alone, of that organism determines the differences alluded to; and I should like to refer briefly to two cases which hardly allow us to acquiesce in such complaisancy; which, added to others that have come under my observation, but from lack of controlling conditions have not been as clean-cut in their clinical portrayal, have convinced me that urethral inflammations due to gonococci may display as wide variations with regard to severity and duration as if they were the result of gonococci, on the one hand, and of simple, non-gonorrhœal irritants, on the other:

Case I.—Profuse, purulent gonococcus, containing discharge from the urethra, beginning a week after exposure; passing through the increasing, stationary, and declining stages, with infection of the posterior urethra and persistence, for a time, of irritative symptoms and the post-gonorrhœal Tripperfäden. Finally, under care and strict abstinence from sexual relations, these disappeared almost entirely in about three months.

Case II.—This patient (the same as above) comes a year later, with a profuse, purulent gonococci, containing urethral discharge, which he says began two days after intercourse. But though he could, and did, account for the attack of gonorrhœa previously related, since it followed an intercourse with a prostitute, this present attack mystifies him greatly. To avoid the possibility of a repetition of his experience of a year ago, he had taken the precaution to confine his sexual relations to an unsuspicious source; but, to make assurance doubly sure, he had used a clean and fresh unbroken condom in the act of intercourse. And yet he has acquired a clap! This attack, however, in proof of the unreliability of the gonococcus as a criterion for prognostication, yields readily to simple astringent medication: and, after a few weeks, not even Tripperfäden are left in sufficient abundance to justify continued treatment.

I have likewise observed cases of traumatic non-venereal urethritis which had lasted for months or years, one in a medical gentleman which had existed at least three years. The conclusion is unavoidable, therefore, that the presence or absence of gonococci is not the sole factor which determines whether an acute urethritis is to be a rapidly healing one, or a never-ending one. And this, as I said, independently of abnormalities such as wide-calibred stricture, narrow meatus, etc., which have held such wide domination in the medical mind as inducers of chronic gonorrhœa. That gonorrhœa requires no such anatomical defect for its indefinite prolongation is evidenced by the numerous cases which we all have in which the most scrutinizing examination fails to disclose any signs of stricture other than the natural variations in the calibre of the organ; or cases in which such variations, looked upon as noxious though natural, are removed by cutting or stretching and yet no relief follows. Consequently, in our endeavor to be both scientific and successful, we must find some other cause that will bear the onus of being a prolific source of chronic gonorrhœa. If "granular urethritis" or "catarrhal urethritis" or "hypertrophic urethritis" or "infiltrating urethritis" be offered as causes to account for the frequent indefinite prolongation of gonorrhœa by such pathologists as Oberländer, they do not satisfy us, as we still wish to know what it is that has produced these several pathological conditions? To be sure, "glandular urethritis" is a pathological condition which also accounts, in part at least, for the prolongation of a certain proportion of gonorrhœas; but the question obtrudes itself on us, even in that case, Why is there glandular urethritis in one case

[1] Read before the American Association of Genito-Urinary Surgeons, Harrogate, Tenn., June 21, 1893.

[2] Legrain: Des Microbes des Écoulements de l'Urèthre, Thèse de Nancy, 1888.

and not in another? So that pathologists with sharply drawn distinctions as to varieties of urethritis have not satisfactorily solved the problem.

Urethral therapists, ardent advocates of new or specific remedies for gonorrhœa, as each has been brought forward, though explaining it on the ground of inefficacy of previous modes of treatment, have each in turn, from time immemorial, failed to establish the fact that the particular mode of treatment or the remedy for which they were then contending would do away with prolonged gonorrhœas. And they have been compelled, one after the other, to admit that it was not always because of inadequate or erroneous therapy that the duration of clap had not been shortened. Have we not but lately witnessed, practically, the discarding of the antiseptic irrigation method that seemed destined to sweep all other methods from the practitioner's hands, not to speak of the successive failures of thalline, resorcin, bichloride of mercury, etc., as efficacious specifics? So that maltreatment or lack of modern medicines and methods cannot account for the continued occurrence of prolonged claps. No more will the condition of general health, conduct of life, hygienic influences, etc., account for the frequency of this condition. These may all be favorable in any number of instances, and yet the evidences of gonorrhœal inflammation do not cease. All of these various factors are the ones to which prolonged gonorrhœa is usually attributed; and though I acknowledge their relatively important bearing, as having a contributory influence, I believe that there is one which is vastly more prevalent, more constant, and more directly influential in the prolongation of clap than any one or even a number of these—a condition that surpasses in frequency, if not in consequences, the much-vaunted stricture or the omnipresent narrow meatus.

I am well aware that infection of the posterior urethra is almost universally recognized, by advanced practitioners of the present day, as a complication of gonorrhœa that is difficult of cure when it does occur; that causes a considerable degree of annoyance to the constantly urinating patient; that interferes with the regular course of treatment which has been prescribed; and that, after apparent recovery, offers secure intrenchment for the baleful gonococcus, which, on being at least temporarily subdued, bides its time for outbreaks a month, a year, or a decade, perhaps, in the future. But I do not believe that the full importance of posterior urethral inflammation is yet generally conceived; that its frequency is even approximately estimated in general, or that its bearing on the treatment of almost every case of gonorrhœa is understood, recognized, or acknowledged.

I do not think it necessary to allude to the far-reaching consequences of infection of the posterior urethra when it does occur as a complication of gonorrhœa; I take it that before this assemblage it would be supererogation to dilate on the opportunities for unlimited hetero-infection afforded by chronic posterior urethritis; on the capacity for indefinitely repeated auto-infection endowed by it; and on the common difficulty of restoring such a urethra to health without direct local treatment, besides its other portentous aspects in the way of arousing reflected irritations, etc. I take it that the important influence, in these various directions, of posterior urethritis, when it does occur, is fully conceded by the gentlemen present; so that if it is a frequent complication, the *rôle* which I would claim for it in the establishment and maintenance of the affection under discussion will be granted as well.

I may say that the degree of frequency with which I estimate infection of the posterior urethra in true gonorrhœa is expressed by the opinion that it should not be looked upon as a complication of the disease occurring exceptionally, but it should be looked upon as a natural feature, occurring with such unfailing regularity that an observer, watching carefully and critically gonorrhœal cases, must see very many of them before he meets with one which remains free from the so-called complication throughout the existence of the disease. I believe that it is practically almost always present, at some time, in cases of any considerable duration or severity. My attention was engaged in this direction some two years ago, and since that time, while I have not had for observation the large *clientèle* that would add materially to the weight of my observation, I have yet observed a very considerable number of cases of urethritis of all degrees of severity and duration; and I have not failed, so far, to demonstrate the existence of posterior infection in any case which displayed either of these characteristics—severity or persistency.

In the cases observed I can disclaim being myself the author of the posterior involvement, as I am not pertinaciously active or over-zealous in early treatment of a gonorrhœa, nor have the observations which confirmed this belief all been based on cases treated by myself from the outset, or even treated by anyone from the outset. They have occurred either in cases treated by internal medication solely, by local medication solely, by both combined, or by neither—that is, lack of any treatment. So that the practically unfailing appearance in these cases cannot be attributed to the form or the kind of treatment, either unduly moderate or inconsiderately severe.

My habit of investigation as to the presence or absence of posterior urethritis in chronic gonorrhœa has been rather searching. I have endeavored not to overlook it in case it were present, as well as to be able to exclude it, were that possible. The double-glass urine test serves me usually, and seldom fails to indicate posterior infection, even when urination has occurred within one or two hours previously. The irrigation test may also be employed satisfactorily. In some cases, however, in which the second portion of the urine is practically clear and therefore not indicative of posterior infection, subsequent study of the case has shown that posterior inflammation was present, rendered manifest by the passage of a bulb-sound into it, or of a soft rubber irrigation catheter, and afterward by the cloudy appearance of the second portion of the urine. The necessity, therefore, for searching investigation in this respect has been made apparent: I do not exclude it on simply the appearance of the urine passed at the first examination.

The classical description of the progress of gonorrhœa represents it as gradually passing from the meatus; following its commencement there is an inflammatory process backward along the mucous surface toward the bulbous portion, which, because of slow progression, it does not reach until about the second or third week (Finger and others). Various reasons are given to explain why it does not readily or usually pass from this portion further backward into the posterior urethra. Guyon says it is because of the resistance offered by the tonic contraction of the cut-off (compressor urethræ) muscle, located just proximal to the bulb, which muscle, as is well known, prevents the ready ingress of fluid, etc., through it. Others[2] point to the paucity of glands and vessels in the posterior, as compared with the anterior urethra, rendering it an uninviting field for the establishment of the inflammation there. These writers, while endeavoring to harmonize as to effects, evidently disagree as to causes; for while Brewer denies the discriminating intelligence for excluding the inflammatory process ascribed to the external sphincter by Guyon, Guyon evidently places as little faith in the alleged paucity of glands of this part of the urethra, as he says[2] the follicles (urethral) are met with in three portions of the urethra; the simple (racemose) glands (*en grappe*) are scattered through the spongy portion and the membranous portion. So our opponents, who should be allies, furnish us with material for the refutation of their own arguments; and were it not that the causes given to account for the presence of this so-called complication are infrequent, we should at once be reduced to the conclusion that this is necessarily a frequent condition in gonorrhœa.

[1] Brewer: Syst. Gen. Urinary Surgery and Ven. Dis., 1893.
[2] Leçons cliniques sur les Malades Voies Urin, 1885, p. 721.

That is, those who argue for its infrequence furnish little reason why it should be infrequent.

The causes they give for its establishment are said to be both internal and external. Representing the former class we have constitutional debility or lack of general resisting power, which, of course, makes lack of local resisting power.

Exhaustion from over-exercise is named as acting similarly. Illustrative of the second class of causes (external) sexual intercourse, the forced or awkwardly administered injection, or the passage of an instrument (catheter?) are chiefly complained of by writers on the subject—extremely seldom by the patients themselves. Indeed, were the posterior inflammation always to await introduction by one of these alleged external causes, it would assuredly be an infrequent complication, since they are not incidents in the vast majority of cases of active gonorrhœa. Gonorrhœa patients are not usually consumptive or diabetic or decrepit from such exhausting diseases; nor are they in the habit of having sexual intercourse in the active stage of the affection, or of passing instruments—that oft-proclaimed but never observed cause for primarily exciting posterior inflammation. Horteloup has investigated the probable influence of the passage of a sound or of a forced injection in such cases; he has experimentally tried them, and without setting up posterior inflammation. The very inadequacy, then, of these several causes as exciters of posterior urethritis is the strongest argument we can discern for its being of infrequent occurrence. And yet clinical investigation shows that it is of frequent occurrence—of exceedingly frequent occurrence. Supporting my convictions as to this point, I have the following statistics of authors who have been pursuing a similar study of late years: Letzel asserts that of 53 cases of primary gonorrhœa under his care the posterior urethra remained unaffected in only 4 cases, making the frequency of posterior urethritis 92.5 per cent. in this series[1]; Jadassohn [2] found posterior urethritis in 143 of 163 cases of gonorrhœa, thus making 87.7 per cent.; Rona[3] declares that it was proved to be present in 79.7 per cent. of his cases; Éraud found it present in eighty per cent. of all (acute and chronic) of his cases.

Ground for belief in the surpassing frequency of posterior urethritis seems, then, to be established, and it remains to harmonize this fact of frequency with the reason for frequency, since that is certainly not done by any of the teachings alluded to. Bearing on this point the time and mode of infection of the posterior urethra are important. We have been taught that the mode is by continuity of tissue, the inflammatory process travelling over the surface of the urethral mucous membrane, gradually approaching the cut-off muscle, which it reaches and passes (if the posterior portion become affected) about the third week.

Again, I would submit the practical teachings of the clinic as confuting the teachings of the text-book; for I have repeatedly observed the proof of the setting-up of posterior inflammation long before the time scheduled for its usual appearance. Rona (*Ibid.*) says that in the cases which he watched, instead of its awaiting the third week of the disease, posterior inflammation made its appearance in the first (active) week in 82.9 per cent. of the cases in which the posterior portion became involved; and Heissler [4] asserts that in twenty per cent. the prostatic urethra becomes affected in the course of the first week, in thirty four per cent. in the course of the second week, in fourteen per cent. in the course of the third week, in twenty per cent. in the fourth week, in four per cent. in the sixth and seventh weeks, and in two per cent. in the second and third months.

These records do not bear out the claim for the gradual progression of the inflammation by continuity to the posterior urethra, but they argue forcibly for the correctness of the theory of Horteloup[1] that the infection is accomplished through the deep lymphatic ducts leading from the anterior to and through the posterior urethral membrane, emptying into the pelvic (internal iliac) glands (McClelland, Gray). If this be really so, it will explain satisfactorily the practical invariability with which the posterior urethra becomes involved, as determined by scrutinizing clinical examinations; it renders plain the small amount of influence played in this regard by the cut-off muscle, or the forced injection, or the alleged passage of instruments, sexual intercourse, etc. These have been uselessly, as well as unwarrantably, invoked to account for the complication that is no complication, but is merely one of the phenomena of the disease gonorrhœa—a phenomenon whose importance, when present, there is no need for dwelling on before you gentlemen, but whose importance through frequency, and therefore in its bearing on almost every case of gonorrhœa, I wish to accentuate.

Conclusions.—1. The causes usually given for the prolongation of cases of clap (presence or absence of gonococci, stricture of large calibre, the use of particular drugs in treatment, etc.) do not satisfactorily explain them, nor do they furnish reliable means for prognosticating the outcome of a case.

2. A single widely prevalent cause for such prolongation of gonorrhœa has, as yet, not proved its right to recognition as such.

3. Posterior urethritis, by reason of its anatomical seclusion and inaccessibility to ordinarily prescribed treatment, if frequent, offers the best explanation for such prolongation or repeated recurrence.

4. Scrutinizing clinical investigation shows posterior urethritis to be present in the great majority of cases of prolonged or severe gonorrhœa.

5. Direct, topical treatment to the posterior urethra is, therefore, necessary in the great majority of cases.

6. The causes usually given for producing posterior urethritis are not commonly found to be real factors in the clinic.

7. The mode of onset usually described does not coincide with that discerned in clinical observations.

8. These two latter observations confirm the probability that the posterior urethral infection is accomplished through the lymphatics, and explain the frequency of such infection.

9. Posterior urethritis is not a complication, but a natural phenomenon, of gonorrhœa.

1006 Olive Street.

Birth in the Coffin.—The *Medical Press* quotes the following singular case from a German exchange: "The patient, aged thirty-five, was attended in labor by a midwife on the 19th of June. The same evening, at 7 P.M., the woman died undelivered. The funeral took place three days later. On the 5th of the following July the body was disinterred on account of an accusation of malpractice made against the midwife. On opening the coffin there was found, 'between the thighs of the corpse, the body of a male child.' There was also 'total eversion of the uterus, together with the vagina.' It is supposed that the decomposing gases in the abdomen of the corpse were sufficient to cause the expulsion of a normally presenting fœtus."

Medical Students in Austria.—Official statistics recently published show that during the winter semester 1892–93 the total number of students of all faculties in the universities of Austria was 13,537. Of these, 5,451 were students of medicine, Vienna heading the list with 2,205, the Czech Faculty of Prague coming next with 1,046; the German Faculty of the same University had 676, Graz, 584, Cracow, 517, and Innsbruck, 323.

MEDICAL CARE AND TREATMENT OF INEBRIETY.[1]

By T. D. CROTHERS, M.D.,

SUPERINTENDENT WALNUT LODGE HOSPITAL, ETC., HARTFORD, CT.

THE "old dogma," that medicine was the art of curing disease, was untrue. If this theory had said that medicine was the art of understanding disease, and relieving and changing the symptoms, modern science would have sustained it. To say that a disease is curable, means that it is self-limited, and the natural tendency is to recovery, both with and without the interference of art. Disease is simply a process of dissolution, running a certain course, controlled by certain conditions.

If we can understand this dissolution process, and the antagonistic influences of the body, we may interpose the resources of art to aid nature in halting the degeneration.

Disease of the brain and nervous system are more complex, and depend on a larger number of causes, which are always more or less obscure. Yet the same evolution and dissolution exist, the same uniform movement following as the result of distinct causes.

In inebriety the problem to determine is this: First. The present condition. The organic and functional derangements of digestion, nutrition, and of the brain and nervous system. Second. The use of alcohol and other drugs and their effect on the nerves and brain. Third. Was the drug and alcoholic addition at first only a symptom or an active causation? Fourth. What neuroses and heredity were the active or latent factors in the natural history of the case?

A study of these questions will point out the line of treatment that will assist toward recovery. A common case will illustrate this more clearly. You are called to see a man who has gastritis, who has taken but very little food for weeks, but has drunk continuously various forms of spirits. Both digestion and nutrition are seriously impaired. General hyperæmia and defective motor and sensory control, and feeble, unstable brain power, are present. If the case is treated from these symptoms alone very little can be expected. If the inquiry goes back to the effects of spirits on the body, and when and under what conditions they are taken, and also the origin of the drink addition, many new indications will appear. If it is found that the use of spirits began from some severe strain or state of exhaustion, or following some disease, or was the result of irregularity in the mental and physical surroundings, further light is added. If the history point to a neurotic inheritance direct, as from alcoholic ancestors, or indirect, as from insane, consumptive, or epileptic, or any of the neuroses, a new view obtains. The treatment of a case that simply checks the brain and nerve irritation by narcotics, or by the removal of spirits, or by elimination removes the congestion and relieves the gastritis, is only partial. Suppose the pledge or conversion, or any moral and mental stimulation, fills the mind with an ardent confidence that he never will use spirits again; or suppose he is given narcotics until the system is saturated, the same effect follows. The mind is buoyed up with the hope that all desire for spirits has ceased, and he is henceforth a free man. All this is empirical, and is neither medical art nor science. A cathartic or narcotic given for some superficial symptoms may do good, and yet it is a mere accident. Moral advice may help the case, and the drink craze may die out; this is also an accident entirely unforeseen.

The inebriate is diseased, and the question of medical care and treatment turns on an exact knowledge of the causation and his present condition.

Such a knowledge will enable the physician to point out the conditions from which a return to health may be expected. He can point to the oncoming insanity of which the drink impulse is only a symptom. He can anticipate the general paresis which is so commonly preceded by an impulsive craze for alcohol. Melancholy suicide, and acute delirium can all be seen in advance, and the more accurately the case is studied, the clearer will be the prognosis. There are no cases that can be more accurately anticipated than these. Certain cases in definite surroundings will have a uniform line of progress that will rarely differ. Take a hundred inebriates and from a knowledge of their heredity, environment, present condition, and the action of alcohol on the brain and nervous system, a prognosis can be made that will be verified in over ninety per cent. of all such cases.

The first question that confronts the physician when called to a case is, What is the present condition and what means can be used to alleviate it? All inebriates suffer from degrees of paralysis, both vaso-motor, sensory, and functional. There is present always functional palsy and subacute inflammation that is generally local. The heart is enfeebled and often enlarged. The liver is congested and the seat of a low grade of inflammation. The stomach is palsied and often acutely inflamed. In cases of long standing, neuritis of the nerves of the extremities in a greater or less degree is present. The first treatment is preliminary, and should begin with a warm bath and thorough rubbing to counteract the vaso-motor palsies of the cutaneous veins and arteries. One of the marked effects of these palsies is to retard and prevent elimination of waste matter through the skin. As a result new sources of danger arise from the chemical decomposition of waste effete matters retained in the system. Ptomaïne poisonings and new sources of irritation, new soils for the growth of bacteria, appear.

The bath is simply a cutaneous stimulant to aid in the elimination of these products. After the bath comes what is termed internal lavage or washing, based on the same reason, viz., as of eliminating the poisonous products which are formed by the paralysis, both functional and organic.

This lavage is best secured by a saline or mercurial cathartic and copious draughts of warm or acid waters. For the nerve paralysis and irritation, the various forms of bromide seem sufficient. I think large doses of one hundred grains at a time are most practical. Of course all spirits are removed at once, and for another purpose, to uncover the real causes which may be masked behind, and appear when the spirits are removed. If profound collapse and acute delirium follows this treatment, I give some form of concealed preparation of opium, usually the deodorized tincture in cinchona bark infusions. This is withdrawn as soon as possible and the bark preparations continued. If digestion is seriously impaired, I give nux vomica in $\frac{1}{10}$ grain doses.

In this preliminary treatment salines, mineral waters, and fruit acids are the common associated remedies. Rest in a recumbent position and passive exercise from massage, together with restraint, are all important. During this preliminary treatment a study of the physiological and pathological history will indicate the causes most active in the craze for spirits. When they are traceable to syphilitic poison and general exhaustion from bad living, a long course of mercury and arsenic, with total change of life and surroundings, are indicated. When the first causes are clearly head injuries, and a slow degeneration from subacute inflammations and other obscure brain and nerve changes appear, very active constitutional treatment with changes of living are essential. Baths, diet, mineral and acid tonics should be alternated with bark infusions. Where traumatism is a distinct cause, all treatment should be based on the prognosis of serious present and future brain trouble.

Where heredity is prominent, the drink craze is a symptom of a constitutional impulse or proclivity to acute degeneration, exhaustion, and death. The same bad prognosis should suggest the most radical changes of life and living, and all medication should be directed to this end. Where this tendency to use stimulants or drugs that are irritant and sedative to the system exists in young persons, a grave future is before them. Often such persons are found in the best families, and will seek ad-

[1] Read before the Hudson County Medical Society, New Jersey, at their semi-annual meeting, April 10, 1892.

vice for some digestive troubles, when it will appear that the real trouble is that some form of alcohol is freely used at the table, or as a family medicine for all disturbances. Where a neurotic heredity is present the future is grave. A recent work on the treatment of children advocates the use of brandy as a tonic in constitutional debility and general anæmia. The author would be astonished if chloral or morphine were urged for these conditions, and yet he advances substantially the same thing. Alcohol to a child is nothing more than a narcotic. A craving for drugs of which alcohol is prominent, is a dangerous symptom. Where the causation of the inebriety has apparently come from exhaustion due to overwork, imperfect nourishment, and general starvation, the treatment must be directed to remove and change these conditions. Where it has started from nutrient disorders, such as indigestion and tissue starvation, the treatment must be based on a careful examination of all the probable complications that exist. The faults of functional and chemical processes of the liver, stomach, and intestines are to be treated as in complex states of dyspepsia. The mental treatment is often of great value, and the physician should always remember that psychical therapeutics are essential in all these cases. Another class will have a clear history of acquiring the drink impulse by contagion, or, more popularly called, bad company, bad example, bad social companions and surroundings.

All such cases will be found defective in both brain and nervous structure. They come from defective race-stock, and have a heredity or neurotic tendency; this, with faulty training, is quickly followed by an unstable brain equilibrium, and consequent exhaustion, for which alcohol soon becomes a grateful narcotic. Such cases are brain defects with central neurasthenic conditions. They need change of every condition of life and surroundings. They should go back to the country and live far removed from every possible strain on the brain and nervous system.

The primary condition in all these cases is failure of the central brain structure. The exhaustion and losses of vital energy are not easily restored by natural processes. Full restoration never occurs, and ever after this want is manifest in weakness, debility, and lowered vitality. Alcohol stills this demand for relief by narcotism and paralysis. The heart's action is raised, then lowered. Currents of blood are driven rapidly to all parts of the system, then slowed down. The temperature is lowered, and the exhaustion that existed primarily is increased. In periodic cases the abnormal brain-force accumulates and is discharged in an epileptic condition, only instead of a spasm attended with tonic and clonic contractions, it becomes an insane thirst for the narcotic effects of alcohol. When this is accomplished, a long period of rest and general anæmia follows. If this insane thirst for spirits can be neutralized and changed, it may be broken up. Fortunately many of these cases have exact and distinct cycles which rarely vary and whose return can be predicted. When this is understood, anticipating treatment can be used. Active cathartics and prolonged hot baths, out-door exercise, where the person leads a sedentary life, or rest where the person is actively engaged, are valuable. Bromide given at night is sometimes of great value. In a case of an active business man in New York, who feels intensely nervous and irritable with his surroundings at distinct intervals, he goes away to the Catskills, tramping for days with dog and gun, and by this means averts a drink paroxysm. A noted physician, who suffers in this way, goes to a hotel, takes large doses of bromide, and remains in bed for several days.

Many and various devices are used by this class with more or less success to prevent the drink storm. The real therapeutic aids should go farther back and seek to avert the causes which culminate in this way. In one case under my care sexual exhaustion was the cause. The man had been a periodic drinker for ten years; his wife died and he recovered, and was temperate for six years. He married again, and a few months later these drink storms returned. Two years later his wife went to New York and was treated six months for an ovarian tumor. He was temperate again and has been so for a year; his wife meantime is travelling in Europe.

These cases are more common than one would suppose, and indicate a neurotic basis to begin with. This periodic return of the drink impulse should suggest some active exciting cause that may be found and corrected. A case was noted by Dr. Brainard, of Columbus, O., where the expulsion of a tapeworm was followed by a total subsidence of the drink impulse. A soldier, who had been a severe drinker for years, recovered after an operation in which a spicula of dead bone was removed. This had existed from the close of the war. The train despatcher of a large railroad, who worked at night and had for many years long and severe drink excesses, recovered by merely changing his work to the day and sleeping at night. A prominent hotel man who has been under treatment will have a drink excess if he remains up at night or past midnight. If he is careful to retire regularly he can remain temperate. Another case has been noted of a quiet farmer who never drinks except after a religious revival. He will take a very active part in the revival meetings, and when they end commence to drink, and be much intoxicated for a week, then suffer from some acute indigestion, and after some medical care recover, never drinking again until another revival comes. Many of these cases only drink on holidays or days of general celebration, and remain sober the rest of the time. Some condition of brain exhaustion exists which is partially controlled until these stated periods of relaxation, when it breaks out again. Such cases need treatment, and often can be cured.

These periodic cases have always a strong tendency to merge into epilepsy and acute dementia. Suicide and homicide frequently are associated. The severe paralysis of the brain in these drink excesses are always perilous to the brain integrity. It is a safe conclusion to follow that the brain in these cases is seriously impaired, and cannot be trusted for sound consistent work. The treatment for this condition is most important, as is also the removal of the active exciting causes.

When the case is that of a continuous drinker, the possibility of general paresis should be considered. Often a prodromic stage of months and years occurs in which the drink impulse will be the leading symptom, then merge into paresis, which speedily culminates in death. The long formative period was noted principally for inebriety, and possibly sexual excess, and slow, growing delusions of grandeur. A noted senator has for two years developed this drink craze, which is concealed as much as possible, yet it is only symptomatic of on-coming paralysis.

These cases are numerous, complex, and are more or less amenable to medical care and treatment. They are medical cases and can only be benefited by medical advice and treatment. The radical changes of life and living can often be best secured in an asylum, where they can come under the constant care of the medical man. The drink impulse is only a symptom, and remedies addressed to this alone are not curative. The case is a constitutional one, to be reached by general remedies, along lines of scientific study. Here, as elsewhere, no specific remedies will be found, for the reason that the causes are so complex, and include all the functions and organic processes of the body. The action of alcohol is equally complex and general, extending to all parts of the body: not only changing the chemical conditions of the nutrition and cell-growth, but paralyzing and breaking up its normal action.

Therapeutic art has not advanced far enough to point out remedies that will reach or neutralize all these diseased conditions. Theories of the action of this or that remedy are open to grave suspicion of error. The more inebriety is studied the more doubtful specific remedies will appear. Only the charlatan and ignorant will ever prepare special remedies for this disease.

In this brief outline of the medical care of such cases, my object is to make prominent the fact that these are curable cases, and always more or less benefited by exact scientific medical care. These armies of inebriates open up a new field for medical practice, one that can show equal triumphs of science and art to that of any other department of medicine. Unfortunately, to-day this realm has not yet been rescued from the mysticism of moralists and quacks. A vast army of squatters, pietists, politicians, and reformed inebriates, are teaching the world the nature and treatment of inebriety. Specifics surrounded with mystery, and urged with the most ignorant dogmatism, are accepted as truths, and the press and pulpit hail their appearance with extravagant praise. Even weak, credulous members of the profession join in the popular current. Medical men, who should be teachers and leaders of public sentiment regarding alcohol and the inebriate, are silent, or carried away by the sentiment of the hour. Over a hundred thousand persons are dying yearly, directly or indirectly, from this disorder, and yet it receives no study or attention except from a class who, of all others, are the least able to comprehend its nature and treatment. It will be a source of wonder and amazement in the coming century, that the medical men of to-day should neglect and show such indifference to one of the greatest scientific topics of the age. We look back a century and find insanity and various epidemics utterly ignored by medical men; given over to the clergy, the politician, and the moralist. History is repeated in the present indifference concerning inebriety. There are over ten thousand physicians in New York State and only a very few have ever given inebriety any study. Yet over half a million temperance men in this country, of all grades, are talking, writing, and teaching what inebriety is and how to treat it. What a terrible sarcasm on our scientific intelligence! A field for scientific work and study is open before us, occupied by quacks and an army of non-experts to-day.

As scientific men but one course remains before us. That is, to study the inebriate and his malady, and teach the public the real facts and their meaning. To assert our true position as teachers, and thus rise above the dense ignorance of the quacks, the clergy, the politicians, the reformers, the moralists, and the inebriates themselves.

Let us show the coming generations that we had some idea of the disease of inebriety and its curability by medical means and measures in this our day and generation.

YELLOW FEVER AND ITS TREATMENT.

By PEDRO J. SALICRUP, M.D.,

NEW YORK.

EX-MEMBER OF THE BOARD OF HEALTH, SAN JUAN, PORTO RICO.

Now that this disease is very prevalent in some of the Atlantic cities of South America, it seems opportune to publish some remarks on its character and treatment, based on my personal experience in a period of twenty-two years' residence in the West Indies.

Yellow fever, which may be now considered as an endemic disease in Porto Rico (place of my residence), used to occur, until the year 1875, only in the form of epidemics, which visited the island at intervals varying from three to ten years, imported from the Gulf ports, generally by vessels proceeding from the neighboring Danish Island of St. Thomas, or from Cuba.

Since 1873, when one of these epidemics occurred, during which I had a large number of cases under my care, the disease has continued to make its periodical appearance every year during the hot season, its extent and malignity varying, as the atmospheric and meteorological conditions of the place favor more or less the development of the germ which causes it. It generally appears first among the crews of foreign ships lying in port, the European troops which garrison the cities, and other unacclimated persons and new-born children, gradually extending to natives who are new residents of the cities, and finally to all persons.

Persons of the African race seem to be less liable to contract the disease than white men, and high localities are generally less frequented by it than low ones, where, in consequence of defective drainage, stagnant waters and decaying organic matters accumulate, which seem to favor the development of the germ. But, as above said, when the epidemic is at its height, it attacks in common Europeans and natives, white and black, and even the highest localities in the mountains, which were considered inaccessible to it, are invaded.

The number of cases varies in each epidemic, and so does the typical form of the disease, as well as the malignancy proper to the type. All or nearly all the cases that occur during an epidemic have the same form or type.

The types or forms which the disease may assume are commonly four, as follows:

1. Inflammatory; in which the predominant symptom is high temperature, which reaches an elevation sometimes of 105° F. from the start.

2. Nervous; in which, in the third stage, the symptoms of cerebral irritation, as delirium, tremor, cold skin, etc., are the most prominent features.

3. The hemorrhagic; in which black vomit and black evacuations are the most dangerous early symptoms.

4. Typhoid; in which the disease, in its third stage, assumes the characteristic features of the affections belonging to this type.

Black vomit is a characteristic and dangerous symptom of the disease and occurs in nearly all the forms earlier or later, though in some rare cases it is absent. The hemorrhagic and typhoid forms are the most severe. The course of the disease is generally divided into three distinct stages:

The first or invasion stage generally begins abruptly with the following symptoms: Chill, high fever, which in some cases reaches 103° to 104° F., supraorbital cephalalgia, lumbar pain, great congestion of the conjunctivæ, general malaise, and a sensation of profound debility. Toward the middle of the second day there is a great diminution of the urinary secretion, which often results in complete suppression, and in the urine a large amount of albumin is found, which is considered to be a pathognomonic symptom. Vomiting is rare in this stage in common cases.

This stage generally lasts three days, after which an intermission or simple remission of all the symptoms occurs, which may continue from one to twenty-four hours, according to the severity of the case. This constitutes the second stage.

In many cases the disease reaches the crisis in this stage, and convalescence is established. In other cases, however, when the patient seems to be progressing favorably, black vomit suddenly occurs and death supervenes in a short time.

The symptoms of the first stage may be mistaken for those of a gastric fever or the invasion of small-pox, which frequently coexists in the locality.

After the remission or intermission which follows the stage of invasion and which constitutes the second period of the disease, the third stage commences. The fever and other symptoms of the first stage reappear, and those peculiar to the form which the disease is to assume are developed. The duration of this stage is indefinite; it may be from three to eight days, according to the severity of the case, but generally if the patient survives after the sixth day recovery may be expected to follow after a more or less protracted convalescence. During the second or at the beginning of the third stage the peculiar yellow coloration of the skin which gives its name to the disease appears.

When the epidemic is at its height some cases occur in which the malignancy of the disease is such that it kills its victims in twenty-four or forty-eight hours. In these cases the dose of the poison which causes the disease, absorbed by the patient, seems to be so large that it causes

a rapid destruction of the elements of his blood, and black vomit sets in early in great abundance, causing the death of the patient by exhaustion. Young and robust subjects are more liable to be attacked by the disease than are weak ones, and they are generally the victims of this malignant form.

The matter vomited in this disease, which is called black vomit, has a very peculiar appearance and resembles very closely the sediment of red wine. The separation of the fluid from the solid element can be noticed at once. It looks more like an exudate than blood, and it exudes from the blood-vessels and through the mucous membranes of the stomach and bowels, and wells out of the mouth of the patient without any apparent effort on his part. This hemorrhage or exudation not only takes place from the stomach and bowels; it also occurs in some instances from the mucous membranes of the mouth, nostrils, conjunctivæ, ears, roots of the nails, or from any blister or wound the patient may have. The matter ejected from the bowels has at the beginning the appearance and consistency of semi-liquid tar, and becomes more liquid as the disease progresses.

In cases that are to terminate fatally there is often an apparent amelioration of the symptoms shortly before death, which lasts a short time and is generally followed by fatal and copious vomiting.

Many papers and works have been written on the causation of this disease, and among these is prominent the extensive work of Dr. Freire, of Rio Janeiro, who pretends to have isolated the germ which causes it; and several commissions have been sent by the governments of this and other countries to the infected localities in Cuba and Brazil to investigate this same subject. Among these is prominent the name of Dr. Sternberg, of the United States Army, but so far no satisfactory conclusion has been reached and the causative germ or bacillus has not been demonstrated. The only facts which seem to have been established are that a low, badly drained locality, a certain degree of heat and humidity of the atmosphere, and bad hygienic conditions favor its development. It has not been determined whether the air, water, or any article of food is the conducting medium of the bacillus.

Authors vary as to whether yellow fever is or is not contagious and infectious. Admitting, however, its bacterial origin (as is generally admitted), and from what I had occasion to observe during different epidemics, I should consider it both contagious and infectious.

I do not know of any remedy which may be called a specific in the treatment of yellow fever. Starting from the accepted theory of its bacterial origin, almost all known antiseptic substances have been employed without any positive results. And although several drugs have been vaunted as having a specific effect by some practitioners, the experience of others has disproved their assertions.

In Porto Rico, where I resided, lemon-juice enjoys a great reputation among the public and is much used in conjunction with other vegetable juices by the laity in the treatment of the disease. I have not seen the wonderful results which are claimed for this popular remedy, but undoubtedly when judiciously used it has a soothing effect on the mucous membranes and in some cases prevents or stops vomiting.

Among the different treatments which I have used and have seen others use, the one which was more successful in my hands was that which I am going to describe:

When called to a case of yellow fever in the first day of the disease I would prescribe ten to fifteen grains of calomel, followed by a saline cathartic three hours afterward, and as soon as the cathartic effect would begin I directed the patient to take a cupful of hot lemonade with five to ten grains of bitartrate of potash every hour until abundant perspiration was produced; this was to be kept up by the constant use of the lemonade and confinement to bed for two or three days, at the end of which time the fever generally subsided and in many cases convalescence was established. No food was given during these days and nothing but small pieces of ice in the mouth was allowed to quench thirst. In cases in which convalescence was not established at once, the symptoms of the third stage appeared after twelve to twenty-four hours, but generally they were less severe and the majority of cases recovered.

In the first epidemic which I attended (1875) this treatment was so successful in my hands that I had a mortality of only about ten per cent. among my patients, who were sailors, and were attended on board the vessels lying in port, while in the hospitals on shore they were having a very heavy mortality under different treatment. In subsequent epidemics I did not find this treatment so effective, but it was always superior to any other when applied early in the disease.

When the disease advanced into the third stage the symptoms were treated on general principles. To prevent or check vomiting pieces of ice swallowed entire, iced champagne, effervescing mixtures prepared with fresh lemon-juice, sulphuric and hydrochloric lemonades, and diluted hydrocyanic acid proved useful in many cases. The salicylates of soda and potash, benzoate of soda, and quinine have been used in cases of the inflammatory type. Castor, musk, or other antispasmodics are sometimes indicated when the nervous system is much disturbed. When the stomach is tolerant and stimulation is required, alcohol and extract of cinchona bark combined is a very useful preparation. Having in view the parasitic origin of the disease, almost all known antiseptic substances have been used internally, but without any marked influence in the course of the disease.

Besides the drugs mentioned, others have been used to meet indications. In some cases of obstinate vomiting or frequent bloody stools the preparations of ergot and other hæmostatics have been employed with variable success; digitalis, scilla, and other diuretics have been given in cases in which the suppression of urine was a troublesome symptom. In cases in which heart-failure threatened, digitalis, caffeine, and other heart stimulants were used by the mouth or hypodermatically. The diet in this stage is iced milk and beef-tea, if the stomach tolerates it. In cases of recovery, convalescence is slow and protracted even in cases in which the disease only goes through the first stage, and the patients remain in a state of chloroanæmia, which takes long to disappear.

Salicylic acid and its preparations are said to have been used successfully as a prophylactic of the disease by some captains of merchant vessels who administered the acid to their crews in five-grain doses three times in the day.

From what has been said the following conclusions may be drawn:

1. That yellow fever is an epidemic disease which has a tendency to become endemic in localities in which favorable conditions for the development of its causative germ exist.

2. That it is of bacterial origin, although the precise bacillus which causes it has not yet been demonstrated; neither has it been as yet discovered whether the water, air, or articles of food used in the infected localities are the conducting media of contagion.

3. That it is probably contagious and infectious, although unacclimated persons and new-born children seem to be more susceptible to the disease.

4. That the blood seems to be most affected, the poison destroying its plastic elements, and it is in consequence of this that the other organic pathological changes which are found in post-mortem examinations are effected.

5. That the disease is more or less severe in different epidemics, according to the form it assumes, and this depends on the different hygienic and meteorological conditions of the affected locality at the time.

6. That there is no specific remedy for it, but that a treatment which promotes abundant secretions of the skin and bowels, if early and judiciously applied, often checks or modifies its course.

HÆMORRHOIDS—A NEW FEATURE OF THEIR SURGICAL TREATMENT.

By J. V. BECELAERE, M.D.,

DETROIT, MICH.

"Quod ferrum non sanat, ignis sanat."—HIPPOCRATES.

THE treatment of ano-rectal phlebectasis, *vulgo* "piles," by cauterization is no doubt almost as old as the disease itself, and it is quite admissible that the father of medicine had in mind the treatment of hæmorrhoids in particular when he formulated his famous therapeutic aphorism: "Quod medicamenta non sanant ferrum sanat, quod ferrum non sanat ignis sanat, quod ignis autem non sanat insanabile reputari licet."[1]

In the course of an interesting discussion following a paper by Dr. H. O. Walker, of Detroit, on the treatment of hæmorrhoids, the statement was made by one of Michigan's leading surgeons that for the last thirty years no progress had been made in the surgical treatment of piles. The trend of opinion seemed to be that, of radical measures, Whitehead's operation was the one most likely to give permanent and satisfactory success. It was argued, however, that in some cases dissecting away the mucous membrane of the anus and inter-sphincterial portion of the rectum is contraindicated.

In 1889 a near and dear friend of mine was suffering with an aggravated form of piles, and I began thinking of a possible treatment—not so much curative as prophylactic.

We all know that hæmorrhoids are dilatations or varicosities of the lower rectal veins, which veins are normally disposed in the shape of loops traversing the sphincter muscle and underlying the mucous membrane in about the same way as the hernial gut hangs out of the inguinal canal under the skin. If a little congestion of these veins occur at an untimely moment, a partial reflex contraction of the sphincter muscle, impeding the return flow of blood, sets up irritation, which in turn increases the sphincterial strangulation. Thus, in consequence of a vicious circle, intermittent contraction soon becomes a fully developed contracture, which opposes all return of the blood retained within the dilated vessel. Continuing this line of thought I fancied that if we could in some way secure a more complete adhesion of the mucous membrane to the underlying muscular layer, destroying, if possible, the submucous connective tissue, we might oppose the recurrence of the hæmorrhoidal nisus and produce a radical cure. Regarding Whitehead's operation it strikes me that one might, perhaps, be satisfied with detaching in a circular manner the mucous lining of the sphincters without resecting the same. I should propose to dissect away from the subjacent muscular sleeve a mucous cuff, which I would forthwith replace in its former situation, and secure by a necessary number of stitches. I believe that in so doing we might obtain the formation of a little cicatricial tissue, just sufficient to secure a more close approximation of the mucous and the muscular layers of the lower bowel, thereby destroying at once the venous loops under the mucous membrane, and the connective interspace wherein they become dilated.

In cases where the knife is contraindicated, either on account of the patient's lack of courage or of previous alarming loss of blood, and, may be, as a matter of fact, in all cases where a surgical intervention is required, I should propose to try what may conveniently be called peri-marginal ignipuncture, and would recommend the following modus operandi: After insuring the benefit of all usual antiseptic precautions, the surgeon should paint over the previously shaved region a sufficient coat of simple collodion, which he should suffer to thoroughly solidify before proceeding any further. This I consider a most sufficient means of avoiding the disagreeable effects of radiating heat. A metallic dilator of convenient size, and filled with cold water, may further be inserted within the anus of the patient postured in the exaggerated lithotomic decubitus.[1] The surgeon then slowly passes the smallest point of a thermo-cautery, at a brown heat, right underneath the mucous membrane of the rectum until reaching the upper sphincter. Withdrawing the instrument he may reinsert it at another point, about a centimetre, or half an inch, distant from the previous puncture. It is a question to be decided

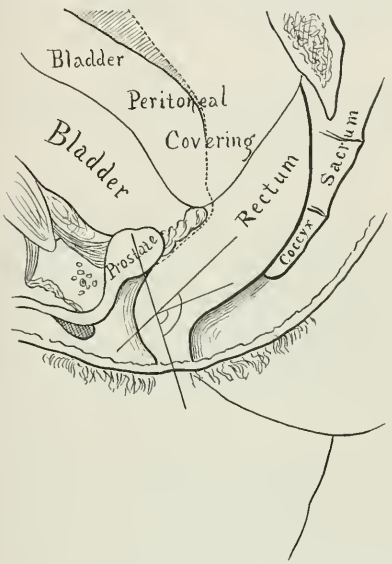

FIG. 1.—Showing how the axis of the sphincter crosses the long axis of the rectum at an angle of 110°. (From Tillaux's Anatomie Topographique.)

only by actual experience how many punctures may thus be made at one sitting; although *a priori* no reason seems apparent for not completing the whole operation at once. A large-sized galvano-caustic needle, constructed "ad hoc" might prove more useful even than Paquelin's instrument, because it could be introduced with the finger in the rectum, the necessary current being turned on with the cautery *in situ*, thus avoiding the danger of perforating the mucous layer.

To my idea the greater difficulty one would meet in trying ignipuncture would be this danger of perforation. But if one keep in mind the natural bearings of the

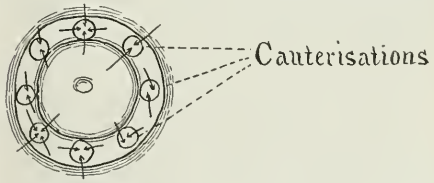

FIG. 2.—Horizontal Section through the Bowel. Inner circle, mucous membrane, outer circle, muscular layer. Observe the direction of the arrows, indicating a concentric retraction of the cicatricial tissue.

sphincterial segment, the main axis of which points directly toward the neck of the bladder, and which, if prolonged, would come out somewhere about the umbilicus, little or no fear need be entertained as to this possible complication. (See Fig. 1.) The capital danger of all orificial surgery lies in the subsequent cicatricial retraction.

Whitehead's operation sometime induces a permanent stricture of the anus; the same is true of extensive surface cauterization; we all know that by the use of the actual

[1] What drugs do not cure, iron (cutting) cures; what iron does not cure, fire cures; what fire, however, does not cure, may be deemed incurable.

[1] See p. 18 of Posture in Medicine and Surgery, published by the Daggett Cable Co., Buffalo, N. Y.

cautery for the "volatilization" of piles, after the method of Richet, of Paris, we may create a cicatricial retraction more aggravating in the long run than the oriignal trouble. If one will consider that all in nodular contraction is concentric, that is, proceeds from peripheral points toward the centre, it will easily be understood how a multiple columnar cauterization cannot in the least influence the calibre of the rectum.

It will be seen by the diagram (Fig. 2) representing the sphincterial region after the operation, how the general tendency would be toward an increase of calibre more than toward contraction.

A NEW APPARATUS FOR THE STERILIZATION OF MILK FOR THE FEEDING OF INFANTS AND INVALIDS.

By LOUIS WALDSTEIN, M.D.,

NEW YORK.

In his dissertation, made under the supervision of Salkowski in 1881, Hoffman found that milk heated up to 70° C. during two hours, coagulated in fine flakes upon the addition of a solution of extract of rennet. I have been influenced by this observation in my mode of preparing milk, during the last ten years, for infant-feeding, and for use in all cases of gastric diseases, including a considerable number of cancers of the stomach. The difference in digestibility of milk prepared in this manner was striking, and the results were satisfactory without exception.

I have been able to watch carefully the development and state of health of a number of children raised by this milk exclusively, and I can safely say that it was far preferable to any other mode of feeding; excepting of course the mother's milk. Such children begin dentition between the fourth and fifth month, and from then on their teeth come without extraordinary disturbances. They steadily grow in weight and corresponding strength, and appear to me normally resistant to the ordinary diseases of children. They do not suffer from constipation, and their stools are normal in color and consistence, while attacks of gastro-enteritis are rare. In cases of typhoid fever, ulcer of the stomach, malignant diseases, and wherever a milk diet is indicated, it is not at all rare to find individuals with whom milk does not seem to agree; but I have never found a case where milk steamed according to Hoffman's experiment, and to which a teaspoonful of a half per cent. solution of hydrochloric acid to each cup is added, the least difficulty is experienced during weeks of an almost exclusive milk diet.

When the results of bacteriological research were applied to the sterilization of milk for artificial feeding, another and most important factor was added to the scientific preparation of this fluid before it could be considered a wholesome food. From that time I adopted the use of the method of Soxhlet; principally because it then became simplified by the introduction of sterilizers which could be easily managed by the mother or the nurse.

It is hardly necessary to enlarge upon the results of infant feeding with sterilized milk, since Leeds has pointed out the effects which continued high temperature has upon the milk, destroying the starch, liquefying the ferment, and modifying the lact-albumin and casein.

My clinical experience has shown me that children of the wealthier classes so fed generally increase rapidly in weight, but are pale, constipated, frequently begin dentition only in the eighth and ninth month, and are generally not so resistant to the common diseases of infancy. I am, furthermore, not quite sure but that several cases of rachitis may not be referred to this food, as one of the exciting causes at least.

It goes without saying that I have carefully followed the advice of Soxhlet, Biedert, and others in the admixtures to the milk. In the above mentioned diseases, moreover, I fail to find "sterilized" milk as valuable as an article of diet as I have found that heated up to 70° C., during two hours, or one hour and a half. For some time past I have adopted, as quite as useful, the last-named period of heating.

It is useless for me here to enter upon a discussion of the great advantage of "pasteurized" milk; Freeman and Koplik have done that work most satisfactorily. I cannot help noting, however, the discrepancy in the results which Freeman publishes in the Medical Record of recent date, between the difference he found in the action of acetic acid and the glycerine extract of pig-stomach, hydrochloric acid, and water on the one hand, and the glycerine extract of pig-stomach alone. In the latter his results resemble those of Hoffman and my own repeatedly made; while the former show no difference in the formation of the curd.

I am convinced that the modification in the form of coagulation is dependent largely upon the length of time during which milk is exposed to the "pasteurizing" temperature. The vomit of over-fed children shows conclusively the resemblance between the curd of human milk and that of milk steamed during the proper length of time.

I have made use of Freeman's "pasteurizer" in several cases, and must say, be it the fault of the nurse or mother, or be it inherent in the process itself, many bottles would not keep perfectly sweet during the whole twenty four hours.

As so much depends upon the simplicity of the apparatus, which must be entrusted to common servants, and as it appears essential that the milk should be maintained at 70° C. for a considerable period of time, longer at all events than that prescribed by Freeman, a fact brought out also by Koplik, I have made use of a patented idea of my brother, Dr. Martin E. Waldstein, in constructing the apparatus which I would herewith recommend to the profession.

The principle underlying it is very simple. It turns upon the reduction and equal maintenance of the temperature of the water in an inner compartment, when it is separated from an outer one in which the water is kept boiling, by an air-space which is larger or smaller according to the difference in temperature which it is desired to obtain. The apparatus is made of tin and is composed of three separate divisions, soldered together in such manner that it is practically of one piece. Between the inner and outer chamber an air-space of one-sixteenth of an inch is interposed, from which the heated air escapes by holes punched in its top. When it is to be used, both compartments are filled with boiling water, the rack containing the bottles is submerged into the inner one up to the milk line, then covered over with the lid and allowed to remain upon the stove during one and a half hour. The milk in my apparatus never reaches a higher temperature than 72° C., never one below 70° C.; the water around the bottles is soon reduced to and remains at 75° C., or a little over, and the water in the outer compartment is kept boiling during the entire time.

It is needless here to enter upon the treatment of the milk and the bottles; such directions are given with each apparatus, and the purchaser is referred to the physician for directions regarding the mixture of the milk chosen with regard to the case, or the age of the child.

Freeman has materially added to the technique of artificial feeding by pointing out the importance of rapid cooling of milk prepared in a like manner. It is, I believe, of very great importance, especially with regard to the separation of fat from the proteid liquid. For this purpose it is required, by the direction for the use of my apparatus, to empty the hot water from both compartments and to refill with cold or iced water, into which the rack and bottles are plunged and kept until used.

I devised and finished this apparatus a year ago, and during this time have fed a number of children exclusively with milk prepared by it, and can only say that my results have been so satisfactory, though necessarily limited, that I can conscientiously recommend it for extended use.

It has been possible to construct it in such a way that it is easily within the reach of the poorer classes, for whom all efforts in this direction are primarily directed.

My experience in pathological cases warrants its further adoption into general practice, and where any difficulty is met with in stubborn idiosyncrasy against milk, the addition of the above-mentioned quantity of hydrochloric acid will prove of great service. Ewald long ago called attention to the value of such addition of hydrochloric acid as a preventive against lactic acid fermentation.

The question how to raise children by artificial means is becoming more and more urgent of solution, because, for reasons as numerous as difficult to properly appreciate, the young mother of our time has no milk, or very little of it, and that very poor, and those classes from which wet-nurses are obtained are fast following her; every physician who has hunted high and low for suitable nurses, and who is as careful as he should be in his examinations of them, will bear me out in the assertion that a wet-nurse cannot to-day be "prescribed," as once it was by our predecessors of a little more than twenty or thirty years ago.

450 Madison Avenue.

REPORT OF THE USE OF SALOPHEN IN TEN CASES OF ACUTE RHEUMATISM.

By D. B. HARDENBERGH, M.D.,

NEW YORK.

PAST INTERNE BELLEVUE HOSPITAL; CLINICAL ASSISTANT, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

The following is a report of a series of cases in the wards of Bellevue Hospital, during the services of Drs. C. L. Dana and J. W. Brannan, in which the use of salophen in acute rheumatism was tested.

Case I.—James R——, aged forty-six, laborer. Admitted December 18, 1892, suffering a mild attack of acute articular rheumatism. Pain, temperature and local signs not marked. Treatment: Salophen, gr. xv., t.i.d. Discharged, cured, in twelve days.

Case II.—James P——, colored, aged thirty-five. Admitted December 31st, with a temperature of 102.2° F. Acute articular rheumatism, with local symptoms well marked. Salophen, gr. xv., was administered, six doses in twenty-four hours.

January 1st.—Temperature in evening reached 105° F.

January 3d.—Temperature fell to normal, and so continued thereafter.

January 6th.—Patient left his bed, was placed on full diet, and in a few days discharged, cured.

Case III.—William McG——, aged thirty, laborer. Admitted February 6, 1893, at 3 P.M. Acute articular rheumatism, with pain very pronounced. Temperature on admission was 102.4° F.; two hours later, 103.4° F. Patient slept but little that night. Salophen, gr. xv., seven doses in twenty-four hours, and five per cent. solution of menthol applied to joints.

February 8th.—Temperature remained below 100° F.

February 9th.—Temperature normal, and so continued thereafter.

February 10th.—Medication reduced to three doses in twenty-four hours, and full diet allowed.

February 13th.—Patient about the ward, and a few days later discharged, cured.

Case IV.—John S——, aged thirty-four, laborer. Chronic rheumatism with chronic endocarditis. Admitted February 17th, while suffering an exacerbation of his chronic troubles. Temperature ranged from 101° to 103° F. Local signs in knee and both hands well marked. There already existed a mitral insufficiency, and the irregular and tumultuous action showed a present active process. With the exception of a rather unusual degree of stupidity, the patient's mental condition presented nothing noteworthy. Salophen was given several days, and then, through failure of supply, was replaced by sodium salicylate, gr. xx., five times in the twenty-four hours. To control the heart action digitalin, afterward the fluid extract of digitalis, was given in ordinary dosage.

February 25th.—Patient complained of a buzzing in the ears, but as the fever and local manifestations had not abated the salicylate was continued. One week later patient developed the delusion that electric wires were strung about the room, and declared he heard continuously their whirring. The salicylate was abandoned but the delusion progressed, and the patient, attempting to escape from the ward and its imaginary net-work of wires was referred to Dr. Douglas, and after the usual period of observation transferred to the Asylum for the Insane at Ward's Island.

Whether the salicylate of sodium merely determined the particular form of delusion, or was an actual causative element to the dementia, is an interesting question.

Case V.—Patrick M——, aged twenty-two, laborer. Admitted February 15th. Temperature, 102.6° F.; acute articular rheumatism. Salophen, gr. xv., seven doses in twenty-four hours administered.

February 21st.—Temperature fell to normal, and so remained.

February 23d.—Patient allowed about the ward, and was transferred, two days later, to complete convalescence.

Case VI.—Frank G——, aged sixteen, laborer. Admitted March 11th, with temperature of 102.6° F., soon reaching 103° F. Acute articular rheumatism. Salophen, gr. xv., every two hours for the first thirty six hours, every four hours thereafter, was given, and the five per cent. solution of menthol applied to joints.

March 14th.—Temperature fell to normal, and so continued.

March 16th.—Discharged, cured.

Case VII.—Frank P——, colored, aged fifty-five, 'longshoreman. Admitted November 30th. Temperature, 101.4° F.; acute muscular rheumatism. Salophen, gr. xv., seven doses in twenty-four hours. Left his bed December 10th; discharged, cured, December 15th.

Case VIII.—Michael D——, aged twenty one, 'longshoreman. Admitted January 24th, with temperature 100.4° F., rising that night to 103.2° F. Acute articular rheumatism. Salophen, gr. xv., six doses in twenty-four hours, with menthol and lead and opium dressings to joints given. Temperature ran normal from January 30th, and on February 7th patient was discharged, cured.

Case IX.—Chone S——, aged thirty-three, tailor. Admitted, February 14th; temperature 101.6° F., rising to 102.6° F. Acute articular rheumatism. Salophen, gr. xv., eight doses in twenty-four hours.

February 17th.—Temperature normal.

February 23d.—Discharged, cured.

Case X.—Matthew B——, aged thirty-one, driver. Admitted March 19th; acute articular rheumatism. Temperature at no time high, but the local signs and the symptom of pain with which the patient suffered intensely the first night were well marked. Salophen, gr. xv., nine doses in twenty-four hours.

March 23d.—Temperature normal; salophen discontinued.

March 25th.—Discharged, cured.

Upon these cases I would submit the following observations:

1. *Dosage.*—Fifteen grains, six to eight times in the twenty-four hours, or from ninety to one hundred and twenty grains in all in that period, may be considered adequate.

2. *Tolerance.*—That no gastric, aural, or other irritant or toxic property was manifested in a single case. Even when given far beyond the ordinary dosage no ill effects were observed. *E.g.*, Case VI., a boy of sixteen, who received two hundred and seventy grains in thirty-six hours.

3. *Therapeutic Effect.*—That the average febrile period after the exhibition of the drug, six and one-ninth days, and average period from admission to date of discharge, less than ten days, attest great curative value. The abatement of pain and local signs were correspond-

ingly rapid. No cardiac complication followed in any case. A five per cent. solution of menthol, absorbed in gauze and covered with oiled muslin, as a local application is a valuable adjuvant.

18 East Thirty-second Street.

Clinical Department.

SOME PECULIAR EFFECTS FROM LARGE DOSES OF HYOSCINE IN A CASE OF ACUTE ALCOHOLISM.

By JAMES PORTER FISKE, M.D.,
NEW YORK.

Of late years hyoscine has been placed before the profession as a valuable hypnotic in conditions of insomnia with delirium tremens, high mental tension, etc. During the past winter I had occasion to treat a gentleman suffering from an attack of insomnia, chiefly due to overindulgence in wine, but also due in a measure to business troubles.

Hyoscine hydrobromate was used, and as the action of the drug was somewhat different from that expected, and as a pure preparation was used hypodermatically, a report of the case will be of value to those who are making a study of the drug's action.

The patient, a man of forty years of age, health good, had of late suffered from insomnia, due to troubles connected with his business. I was called to see him on a Sunday evening, and learned that he had been drinking constantly for some days and nights. He was very restless, walking up and down the room, lying down for a minute and then starting up again. When walking, his gait was good. His speech was articulate, and most of the time intelligent. He was apparently very nervous, and begged for something to put him to sleep. At times he would see about him the faces of friends and with them he would converse.

11 P.M.—Gave hyoscine hydrobrom., $\frac{1}{100}$ grain, hypodermatically; absolutely no effect in forty-five minutes. The dose was repeated and then I had to leave the patient.

I was called the next morning at half-past seven. He had dozed for half an hour after receiving the second injection, and had then returned to his former condition of extreme restlessness. I determined to continue the use of hyoscine, and decided to give larger doses, and obtain a marked action from the drug if possible.

8 A.M.—℞. Hyoscine hydrobrom., $\frac{1}{60}$ grain, hypodermatically. In fifteen minutes the patient complained of his extremities feeling peculiar, somewhat "numb and prickly." His hands assumed a purplish hue, and felt cool. He rose from the bed and attempted to walk, but after going about four feet his legs gave way, and he fell to the floor, though up to this time, in walking, his gait had been good. He complained of great weakness in both legs. He turned to me, and in a husky voice, hardly articulate, told me that these symptoms were due to the drug I had just administered. In a few minutes he again attempted to walk, and after tottering a few feet again fell.

I watched him carefully and noticed that his speech had become confused, markedly difficult, his voice husky. The pulse was 90.

In two and one-half hours, at 11 A.M., his hands had returned to their normal color, his walk was again steady, speech was clear, and his legs "felt all right again." During these hours he at no time felt inclined to sleep. No other drug had been administered. He had had but one half hour's sleep in forty-eight hours, was in great mental distress, and begged to be put to sleep. I gave him morphine sulph., one-half grain, and left him.

I returned at 5 P.M., and found him awake and restless. He had slept one-half hour after the morphine. He saw about him familiar persons with whom he engaged in conversation. In a moment he turned to me, and said that he knew the faces were hallucinations.

I determined to try hyoscine again and see just what the action would be on him. His condition at this time was as follows: Pulse, 96; respiration, 20 and regular; very restless. In walking, his gait was good. His speech was clear and intelligent as a rule. His only hallucinations were when he engaged in conversation with imaginary faces. He was constantly changing his position, starting up and then sitting down.

5 P.M.—Hyoscine hydrobrom., $\frac{1}{60}$ grain, hypodermatically. In a few minutes he attempted to rise, did so with difficulty, and taking one step sank to the floor. He complained of great loss of power in both legs; speech was difficult (inarticulate). Respiration was slightly irregular and labored. His extremities again felt dumb; his hands and face were markedly purplish and dusky. Pulse, 112. No feeling of sleepiness. These symptoms gradually disappeared in three hours without treatment.

At no time had the hyoscine produced a hypnotic effect; the chief effects being motor paralysis, as indicated by loss of power in the extremities, sensory disturbances and impairment of speech, with some circulatory disturbances. I then put the patient on chloral and bromides in large doses, followed by the hypodermatic use of atropine and strychnine, with very favorable results.

This case is of more than passing interest, as it has been very generally stated that in alcoholic mania and in the insomnia of acute alcoholism hyoscine is of the greatest value.

328 West Fifty-seventh Street

A CASE OF MYXŒDEMA—THREE AND A HALF MONTHS' TREATMENT WITH THYROID GLANDS.

By ETHEL D. BROWN, M.D.,
NEW YORK.

The patient whose history follows has been given one or more thyroid glands twice a week since February 14, 1893.

The glands were prepared as follows: All the fat and muscles were carefully removed, the capsule taken off the gland, and then half the amount to be given finely minced; the other part was cut in small pieces, allowed to macerate in two or three drachms of water for half an hour. The juice was then extracted by pressure and filtration through a piece of cheese-cloth, and the juice so obtained was mixed with the minced portion.

The first and second time this mixture was taken a half-drachm of whiskey was added; afterward beef-tea and salt were substituted for the whiskey.

The entire mixture varied in amount from f ʒ j. to f ʒ jss. each time. The patient did not object to the taste, and no unpleasant symptoms followed the administration of the glands.

E. K——, female, aged forty-five years; born in Ireland; a lithographer by trade.

The family history as obtained is not very exact. Her mother died in old age of "old-fashioned decline," one brother died of phthisis, and another of some chronic lung disease—the patient did not know if it was tubercular or not.

The patient considered herself perfectly well until twenty years ago, when she began to suffer from attacks of severe abdominal pain. The physician consulted at this time told her the illness was the result of her occupation.

She worked at her trade as her health permitted until ten years ago, when she had lead paralysis. On recovering from it she was well for five years, and during these five years worked again at her trade.

Five years ago she claims to have had dropsy, which disappeared under treatment at one of the city dispen-

saries, but the patient never felt well enough to return to work.

When first seen by me, September, 1891, the patient merely complained of a feeling of weakness. There was some swelling of the extremities, but no pitting on pressure. The urine was of a sp. g.of 1.008; trace of albumin, but no casts. From this time up to the commencement of the present treatment the symptoms of myxœdema steadily appeared in spite of the fact that the different medicinal treatments were tried.

The following notes were taken the day the first gland was given.

Temperature, 97.6° F.; pulse, 82; respiration, 24. Eyes seemed small, being partially closed by the puffiness of the cheeks; lines about the face were almost obliterated; constant occipital headache; the lips were thick and protruding; there was marked swelling over both clavicles: the skin was dry and rough, and the patient did not perspire at all; the nails were brittle; the hair had fallen out to such a degree that the scalp was plainly visible; the eyelids were almost devoid of eyelashes. The patient had grown much stouter; the legs were apparently swollen, but there was no pitting; there was a small superficial ulcer on the anterior portion of the left leg. The patient walked slowly, with a waddling gait, complained of always feeling chilly, and was cold to the touch. She could not keep awake, and when left undisturbed sat in her chair apparently dozing. She spoke in a slow, hesitating manner, and could neither hear nor see as well as formerly. Her memory was poor, and neither the sense of touch nor that of taste was normally acute.

The urine at times had contained a trace of albumin, but never any casts. Miss Chevalier, Professor of Chemistry and Urinary Analysis at the Woman's Medical College of the New York Infirmary, kindly examined the urine several times, and never found a trace of mucin.

The patient said she felt better when the second gland was administered, February 17th, but no change was noted until March 1st.

At the present time the patient says she has not felt so well in five years. The scalp is covered with a new crop of hair about three-fourths of an inch in length; the eyes seem larger; the lines about the face are visible, and the lips are not protruding. The patient is much thinner, but there is still some fulness over the clavicles. She is able to walk firmly and for some distance without tiring. She feels warm. She can hear and see as well as ever, and seems to be in a fair way of regaining perfect health. The treatment is still continued, and it is still a question if it will not always have to be kept up at intervals.

THE HÆMOSTATIC PROPERTIES OF PUFF-BALL.

By A. L. HALL, M.D.,

FAIR HAVEN, N. Y.

The mention of the surgical uses of puff-ball (lycoperdon giganteum), made on page 783 of the last volume of the Medical Record, recalls to mind my experience with this agent, a part of which I will briefly relate, with the hope that it may prove of some interest.

For a great many years, how long tradition does not say, puff-ball has been successfully employed by the laity as a hæmostatic. In my early boyhood, I occasionally saw the milder forms of hemorrhage promptly controlled by its use. On one occasion, an obstinate flow of blood from an incised finger was quickly staunched by the application of pieces of puff-ball to the cut surfaces, made at the suggestion of an elderly lady who had long cherished its virtues. These lessons of my youth might have never found a useful application in my practice, had it not been for an almost accidental occurrence, as it were, which took place in 1888. At the time named, I was called to attend a case of severe epistaxis resulting from a purpuric condition, occurring at the end of the third week of a typhoid-fever illness, in a young man of good habits. The blood came from the nostrils in heavy streams, and had been in progress for fully one-half hour before I saw him. The nares were douched with ice-water and a strong solution of iron persulphate, and compression was tried without relief. The nares were then plugged, anteriorly and posteriorly, with pledgets of cotton saturated with persulphate of iron, but with only partial success, the fluidity of the blood permitting oozing to occur in spite of these measures. At this moment an enormous puff-ball, more than a foot in diameter, was brought to the bedside, and I determined to make use of it. Removing the anterior plugs, I filled the nares completely with loose pieces of puff-ball, after which I restored the plugs of cotton, when all signs of hemorrhage ceased and did not again recur. The tampons were removed at the end of the second day, and by the end of the third day the nares were opened, the pieces of puff-ball being easily dislodged, its presence in the nares being unattended by any ill results.

In another case, a lady sixty years of age, a profuse and alarming hemorrhage occurred from the anterior and posterior nares, which was promptly checked by filling the lower nasal cavities with puff-ball, the cotton plugs being omitted. Later, the nares were cleansed with douches of hot water and all traces of the puff-ball were thus removed without any unpleasant effects resulting then, or subsequently, from its use.

Recently I tried for nearly thirty minutes before success rewarded my efforts to arrest a free hemorrhage resulting from a tooth extraction, made by a neighboring dentist, which had continued for several hours, and had reduced the patient to the verge of syncope. Applications of ice to the gums, packing the cavity with styptic cotton and puff-ball, and the addition of a ligating compress over the aperture only partially restrained the flow of blood. A more careful search revealed a separation of the gums from the inner border of the lower maxilla in such a way as to lacerate the alveolar branch of the sublingual artery, the blood welling up through the tooth aperture, thus giving the impression that the hemorrhage was due to a rupture ot the inferior dental artery. A packing of styptic cotton and puff-ball into the pocket made by the separation of the soft structures from the bone, quickly and effectually arrested the bleeding. In this case, I observed that the hæmostatic property of the puff-ball was equal to, or even greater than that of the styptic cotton, while it appeared to adhere more quickly and firmly than did the cotton styptic.

In concluding, I would say, that as a hæmostatic for controlling the severer forms of epistaxis, I believe it has no equal. I have such confidence in it for this purpose that I am, now, never without it. I believe that no valid objection can be raised against its use on the ground that it is not sufficiently aseptic, while, on the contrary, it is to be preferred to many other hæmostatics on account of its non-irritating qualities.

Antipyrin in Typhoid Fever.—Dr. Roussel, of the Hôtel-Dieu, St. Etienne, has published a long and interesting article on the treatment of typhoid fever by antipyrin given in increasing doses, thus avoiding all danger of collapse. He commences by ten grains four times a day dissolved in pure, unsweetened water, leaving three hours between each dose. The following day he gives twenty grains, morning, noon, and night. On the third day a drachm is given in four doses, and an increase of twenty grains ordered each day until two drachms are attained, leaving an interval of two hours between each dose. On the outset of the treatment the fever diminishes, but not for long, as it goes up again in spite of the increasing doses, until a drachm and a half of the antipyrin is given, when it abates definitely. No other treatment is ordered save the usual *régime* of typhoid patients. Out of ninety-three patients thus treated, Dr. Roussel did not lose one.—*Medical Press.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, July 29, 1893.

DR. FREIRE'S OPPORTUNITY.

RECENT advices from Brazil bring word of the continued ravages of the epidemic of yellow fever in Santos, an epidemic which for its protracted duration and the fearful number of its victims is, perhaps, unparalleled in the history of this disease. It is now two years or more since the first reports of the scourge were brought from that fated city, and to day there seems to be no abatement in its fury, the daily mortality still reaching up into the hundreds. The brig Odorilla recently arrived in Philadelphia from Santos with only one surviving member of the original crew, Captain Holland, the others all having succumbed to yellow fever. The vessel was under charter to carry to Santos a cargo of locomotives. When she arrived in that plague-stricken port, on May 25, 1892, she was docked three hundred and forty-two days before the necessary hands could be secured to discharge her cargo.

Captain Holland's descriptions of the misery and sufferings from yellow fever in Santos are heartrending. Thousands have been stricken with the disease and have died. Business was at a complete standstill, and there were forty-five vessels lying in the Santos River without their crews. Anchored near the Odorilla were fully twenty vessels, everyone of which had lost her captain. The London and Brazil Bank closed its doors shortly before the Odorilla left, everyone of its employees having been carried off by the scourge. The Brazilian and South American Bank was compelled to do likewise. The members of the firm of Messrs. Zerener, Bulow & Co., consignees of the Odorilla, have nearly all died.

On March 3d, Charles Wadsworth, the American Vice-Consul, died, and as Mr. Berry, the Consul, was ill with the disease, and all the clerks were dead, the consulate was closed. Captain Holland believes the entire port will in a short time be completely depopulated. While the Odorilla lay at Santos the daily death rate averaged 310. Hundreds of corpses were afloat in the river in all stages of decay. The Government, it is said, has exhausted every means looking toward a suppression of the spread of the disease. Three large hospitals have been erected for the care of those stricken with the fever, and they are crowded to their utmost capacity. The patients die more rapidly than their bodies can be disposed of. No services are ever held over the bodies of any of the unfortunates, and they simply are thrown into long trenches, and barely covered with a shovelful of earth.

Dr. Domingos Freire, a distinguished physician and scientist of Rio Janeiro, who has made a long and painstaking study of yellow fever, claims to have discovered the specific micro-organism of the disease, and has prepared from cultures of this bacillus a preventive vaccine by means of which he believes that he can render unacclimated individuals immune to yellow fever.

These claims have not received general acceptance, and are flatly disputed by many, among whom is Surgeon-General Sternberg, of the United States Army, who has studied Freire's methods in the latter's laboratory and rejects his alleged discovery of the microbe of the disease as unproven. This rejection gave rise to much controversy, less, perhaps, on the part of the principals than on that of their followers, which is even yet unstilled. Dr. Freire has reasserted his claims in a *brochure* published within the past year, and only a few weeks ago an active correspondence was going on in the pages of a contemporary between the friends of one and the other party to the dispute.

It seems to us that here is an opportunity for Dr. Freire to prove the correctness of his theory and the validity of his claims to the discovery of a preventive vaccine, which will be far better and more convincing than the shedding of gallons of ink. Let him induce the Brazilian Government, in an auspicious interval between revolutions, to send him to Santos, with full authority to practise his inoculation upon all who are willing to submit themselves to the experiment, and as drowning men will catch at straws the wretched survivors of the plague in Santos will doubtless be only too ready to take advantage of anything that promises them immunity. Then let Dr. Freire go to the doomed city with his assistants and establish his laboratory there and vaccinate all who come.

If he succeeds in rendering the remaining inhabitants of the place proof against the attacks of yellow fever, the plague will be stamped out and the name of Dr. Domingos Freire will go down the ages along with that of other great benefactors to the human race. And his fame will not be posthumous, but he will have the happiness of hearing his praises sung throughout the world, and honors will be heaped upon him in numbers to satisfy the most ambitious. This is Dr. Freire's opportunity, and our only wonder is that he has not before this recognized it and made it his own.

PULSUS PARADOXUS IN ACUTE LARYNGITIS.

By this term is understood a distinct diminution during inspiration of the tension and height of the pulse wave. At one time it was regarded as distinctive of mediastinal inflammation, but has since been observed in pleural effusion, mediastinal tumors, and aneurisms of the thoracic aorta. Griesinger, who first called attention to it, attributed it to the direct action of newly formed tissue adherent to the sternum and pulling upon the aorta. Jurgensen also, has noted a diminution of the strength of the radial pulse in inspiration during a pneumonic seizure.

Brockbank has recently called attention, in an interesting article,[1] to the occurrence of this phenomenon in children suffering from dyspnœa due to laryngitis, either membranous or simple. In nine cases, he observed it in every instance, provided the laryngeal obstruction was

[1] British Medical Journal, June 24th.

sufficient to cause recession of the intercostal spaces during the respiratory act. As the dyspnœa increased this peculiarity of the pulse became more and more marked, until just before tracheotomy was done in cases requiring it the pulse became almost imperceptible during inspiration. As soon as the trachea was opened and the pulmonary tissue received its due supply of air, the phenomenon disappeared.

Brockbank believes that it is possible by this pulse variation to measure approximately the amount of laryngeal obstruction. It is not necessary, therefore, in a cold room to strip the child's chest to notice the recession. When the symptom becomes more marked without an increase of recession, operative help is indicated.

He does not attach any prognostic value to the pulse in acute laryngeal inflammations, nor does he believe that its variations can be invoked to distinguish between the various pathological varieties of this affection.

The cause of this clinical feature he finds in the great variations of the intra-thoracic pressure on the heart and large vessels. When the chest cavity is suddenly enlarged and the air does not pass through the glottis rapidly enough to fill it, the negative pressure which is always present at the commencement of inspiration is prolonged throughout the entire inspiratory period.

"The manner," he adds, "in which the increased negative pressure in the chest determines the variation in the rhythm and volume of the pulse may be briefly summarized. The blood in the vessels of the body, generally, is subjected to the action of the constant positive pressure of the atmosphere, so when a partial vacuum is created in the thorax there is a tendency for the blood to be aspirated into the great vessels there. This aids greatly the venous circulation of the body, but at the same time must of necessity tend to hamper the flow of blood in the large arteries. The two results to some extent counteract each other normally. The thin-walled auricles are more affected by the aspirating action of the negative pressure than are the ventricles; and here again the venous flow is aided, so that the heart receives a plentiful supply of blood—in fact, the contents of all the great veins and arteries near the thorax tend to flow to the heart.

"The ventricles receive the blood from the auricles, and on contracting, the right side of the heart forces its blood without impediment through the lungs to the left side. It is on the left ventricle that the full force of the extra work falls, for it has to overcome, not only the normal pressure in the arteries, but also the tendency of the blood in the large arteries to flow backward in the direction of the negative pressure. In other words, the heart has to pump blood out of a vacuum into positive pressure. This negative pressure is normally only slight and transient in its effects on the blood flow, but in abnormal conditions, such as laryngeal stenosis or forced inspiratory movement with the mouth and nostrils closed, it is much more marked, lasts longer, and acts visibly on the volume and rhythm of the pulse, producing the pulsus paradoxus.

"It is probable, therefore, that increased work is thrown on the heart in cases of acute laryngitis; and when this important organ is weakened as a result of the pyrexia and of the virus of the disease, it naturally tends to show more signs of failing as the disease progresses."

Finally, he suggests that in children with a flexible sternum and an extreme amount of chest recession, direct pressure on the heart from the retracted sternum may cause the feebleness of the former. It is well also to remember that pulsus paradoxus occurs occasionally in healthy individuals (Riegel), and that it can generally be induced in the latter by the subject closing his mouth and nose and then rather forcibly endeavoring to draw in his breath.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

In connection with the fact, as stated editorially in the *Journal of the American Medical Association*, that "the total membership of the Association has steadily decreased for the last five years, until it is now fifty per cent. less than it was in 1888," it is unaccountable that a measure, that can only result in further loss of membership, and of a membership of the very highest professional character, should be seriously contemplated; yet at the last meeting an amendment to the constitution was proposed which will have the effect of driving away the entire representation of the Medical Departments of the United States Army and Navy and the Marine Hospital Service. The paragraph in question reads:

"Membership shall be limited to members of the several affiliated State Medical Societies recognized thereby or represented therein. As membership in these societies is open to all reputable practitioners in each State, the membership in the American Medical Association is open to all reputable physicians in North America."

As the three organizations referred to are wholly national in character, and their membership in no sense connected with State organizations, and as the Medical Departments of the Army and Navy have been integral parts of the Association from its very organization in 1846, their members naturally resent, and in this the later organized United States Marine Hospital Service is in hearty accord with them, what many of them feel to be only a thinly disguised attempt to compel them to subscribe to a Code of Ethics which, it has been their boast, has not been necessary to preserve their reputations as honorable officers, gentlemen, and medical men.

THE GREAT ENEMIES OF MAN.

The change in the conception of tuberculosis, produced by a discovery of its true cause, calls for a reconstruction of many of the heretofore approved statistics of mortality. It is not very long ago since text-books stated that tuberculosis, meaning especially pulmonary consumption, affected most often persons between the ages of fifteen and thirty years. The tubercular infection is now known to be most frequent as a cause of death in infancy. At this time it is the mesenteric and other lymph-glands and the meninges that are involved; in childhood the bones are prone to be attacked, in adult life the lungs.

Taking tuberculosis in every form as a cause of death, Professor Hugo Holsti, of the University of Helsingfors, has compiled interesting facts showing the relation of age to this disease.

During the years 1882–1889 there died in the Swede-Finnish district of Helsingfors 1,771 persons, of tubercu-

lous diseases. The mortality rate per 10,000 living persons is much the greatest during the first two years of life (2.5 per cent.). It rapidly falls until, between the ages of six and fifteen, it hardly exists (about .15 per cent.). It then steadily rises until the decades thirty-one to forty, forty-one to fifty, and fifty-one to sixty, where it remains at about .6 per cent. and then falls again.

Males are more subject than females in the proportion of 990 to 781, but this holds true more for adult than infant life.

Professor Holsti's tables show in a striking way identity of the period of greatest mortality from tuberculosis with the time when children are fed on milk.

May it not be that after all the cow is the great enemy of mankind, and that without the cow there would be no tuberculosis? The history of Japan, which is a cowless country, favors in a measure this view. Science seems to be pointing toward the conclusion that there are two great and potent poisons constantly diffused among civilized peoples, and these are milk and water. Not that these substances are essentially bad, but that they are accidentally so. It is not proposed to abolish, but to purify them.

News of the Week.

Anti-Vaccination Cycles and Their Results. — It is curious how these anti-vaccination movements come as it were in cycles. The last great movement was in Germany. Wurtemburg and Baden were the Leicesters of those days, and so effectually did they preach the anti-vaccination doctrine, that it found a ready acceptance in all the populous manufacturing districts. The yearly vaccinations rapidly decreased, and the difficulties in carrying out the regulations became greater everywhere. From Germany the revolt against vaccination spread to Italy, and vaccination held for a time a very questionable position. The victory of the anti-vaccinators was, however, of short duration, for there swept over Germany in 1870, and from thence into other countries, one of the most destructive epidemics of small-pox known in this century, and people learned from a disastrous experience that until more is known concerning the origin of small-pox, the only safeguard is vaccination. The most remarkable outcome of this epidemic in Germany was the disappearance of the opposition to vaccination, and those who had been loudest in its denunciation were among the noisiest to demand a law by which not only vaccination but re-vaccination should be rendered compulsory.—*Indian Medical Gazette.*

What the London Hospital Fund Has Accomplished. —In view of the fact that this year the Hospital Sunday Fund attains its majority, the Lord Mayor has presided over a special meeting of the fund at the Mansion House. It appears from the report of the secretary that since the commencement nearly £700,000 has been obtained, last year's contribution being £41,512. His Lordship credited the happy idea of the fund to the late Canon Miller, of Greenwich; and he pointed out that, large as had been its success, some of the hospitals had been obliged to close their wards for want of means. Cardinal Vaughan stated that more than 1,200,000 persons were treated in metropolitan hospitals last year, at a cost of £677,000, and that 1,741 congregations made collections—a number considerably short of the total in London.

Clinical Teaching at Berlin.—The attempt to induce the Corporation of Berlin to open their hospitals for clinical teaching has not been successful. This is the more to be regretted as the Charité is overloaded and hardly up to the high standard of accommodation for teaching purposes which is recognized as necessary here. The university has splendid buildings devoted to surgery and the diseases of women, and doubtless ways and means will be found before long to give medicine equal advantages.—*British Medical Journal.*

The Philadelphia Quarantine has passed from the control of the Board of Health to that of a Quarantine Board of seven persons. In the constitution of this board, two non-official bodies, the College of Physicians of Philadelphia and the Maritime Exchange, have a voice, each appointing a member. The bill abolishes the double-headed system by which the Port Physician and the Lazaretto Physician took turns, so to speak, at the duties. The useless office of Quarantine Master is also abolished, as is also all payment of fees to the officials, a reform that is highly commendable. The most important feature of the bill, however, is the provision made for the substitution of National for State quarantine. The act empowers the Governor to suspend the whole State system whenever he is satisfied that an efficient quarantine is maintained by the Federal authorities.

Progress in Medical Education.—President Eliot, of Harvard University, in his speech to the Alumni on Commencement Day, announced that the Law School had raised its standard by requiring, after the year 1896, the degree of A.B., S.B., or Ph B., as a prerequisite for admission to its courses. There is already such a requirement in the Divinity School, and President Eliot expressed the hope that hereafter it would be adopted for the Medical School.

Two Little Poems.—

The Cut Direct: "For years he was well known to me,"
So the physician sadly said,
"But now, called to his autopsy,
I am obliged to cut him dead."—*Brooklyn Life.*

His Sorrows: He read for a time with pleasure,
Then he began to grow mad,
He had dropped a tear for the heroine's woes,
And found it a medicine ad.—*Chicago Inter-Ocean.*

Progress of the Cholera.—The outbreak of cholera at Mecca has evidently been very serious, for the total mortality among the pilgrims since early in June last has been upward of five thousand. The severity of the epidemic is stated to have somewhat declined of late, although the number of fresh attacks and the death-rate still remain high. On July 3d, 260 deaths from cholera occurred at Mecca and 490 at Jeddah. These large gatherings of Mussulmans are a recurring source of danger, and the arrangements for them should be placed under Government control, as is done in the case of the great religious fairs and pilgrimages in India. In addition to the evils of dirt and overcrowding, the pilgrims are usually exhausted from fatigue and want of proper food, their

water-supply is probably both bad and inadequate, and there is, speaking generally, an absence of all sanitary and medical arrangements.

The report that cholera exists at Alexandria, in Egypt, is denied. In reply to a despatch of inquiry, Surgeon-General Wyman, of the Marine Hospital Service, received on July 15th a message from United States Consul Ewing, at Alexandria, saying: "There is absolutely no cholera in, or in the vicinity of, Alexandria."

Revoked Charters.—The Board of Regents of the University of the State of New York have recently revoked the charters of the "College of Midwifery of the City of New York," and the "College of Massage," two institutions under the same management.

A Boylston Medical Prize for 1893 has been awarded to Drs. William E. Hughes and William S. Carter, of Philadelphia, for an essay entitled, "A Clinical and Experimental Study of Uræmia."

Treatment of Syphilis by Injection of Blood-serum.—Professor Tomassoli, of Modena, has recently published an article in a Vienna medical paper in which he maintains that he has obtained excellent results by treating cases of secondary syphilis with injections of the blood-serum of the lamb and calf. Thirteen patients were treated by him in this way, and were cured, as he stated, within a few weeks. From two to eight cubic centimetres were injected into the muscles with a Tursini's syringe on each occasion, the total number of injections varying in different cases from six to thirteen. The only obvious effects of injection were slight fever, pain, and local induration.

Immunity in Diphtheria.—The experiments which Behring, in the Institution for Infectious Diseases, and Aronson, in the Laboratory of the Agricultural College, Berlin, are conducting with the object of providing a serum, or a product from serum, which can be used in convenient doses for the treatment of diphtheria, have been attended with a very considerable degree of success; but it appears that there are great difficulties in raising the degree of immunity sufficiently high and at the same time preserving the animals in health. There can, however, be little doubt that sooner or later the zeal and talent of these experimenters or some of their fellow-workers in the same field will be rewarded, and that we shall have, in a convenient and reliable form, a specific remedy against one of the most fatal diseases.

The Successor of Professor Kahler.—At the last meeting of the "Professors' College" of the Medical Faculty of Vienna, Professor Naunyn, of Strasbourg, was proposed as successor to the chair of Medicine, vacant by the death of the late Professor Kahler. Professors Epinger, of Gratz, Chiari, of Prague, and Weichselbaum, of Vienna, were nominated for the vacant chair of pathological anatomy.

Dr. G. Sterling Ryerson, Secretary of the Association of Medical Officers of the Militia of Canada, has been appointed by the Queen an Honorary Associate of the Order of St. John of Jerusalem, for services in connection with ambulance work in the Riel rebellion.

The Medical Department of Columbia College (College of Physicians and Surgeons) will put its four years' course in operation next year. It is gratifying to learn that the percentage of college-bred men who enter this institution increases as the standard of instruction is raised.

Electrolyzing Drinking-water.—There is always something mysterious in the uses of electricity, but the project our city has undertaken, of purifying 120,000,000 gallons of Croton daily by electrolysis is particularly weird. It is all done with a couple of five horse-power dynamos and a 1,000-gallon electrolyzing tank.

Accused of Selling Diplomas in Medicine.—Dr. Walter May Rew, of this city, who has run what he calls the Preparatory College of Medicine, was arrested recently on a warrant accusing him of selling diplomas in medicine at from $25 to $50 each. A large quantity of blank diplomas and seals were found in his rooms. The diplomas, it is said, entitle the holders to practise in several Western States.

Favus is not a pleasant disease, and its importation is not a thing to be desired. Yet it is curious to find our immigration authorities so sensitive in the matter of keeping out favus-stricken immigrants. One case of syphilis or phthisis, or one thorough-going anarchist will do more harm to the body politic than forty cases of favus. For the disease is curable, and it is so conspicuous that the sufferer is generally forced to seek relief. As favus is so often transmitted by dogs, cats, and mice, it might be well to investigate the importation of these animals.

A New Non-poisonous Disinfectant, Izal.—This substance is of English origin, and the *Lancet* for July 1st states that it has been approved by Dr. Klein, biologist to the Brown Institution. It is derived from an oil that appears as a residuum from coke-making at the collieries, especially at those situated at Thorncliffe, near Sheffield. As a destroyer of germs, izal takes a higher rank than carbolic acid, but is non-poisonous, unless the quantity ingested is very large. Extensive experiments in Dr. Klein's laboratory tend to show that one part of izal in two hundred parts of water is capable of destroying the micro organisms of diphtheria, scarlet fever, glanders, erysipelas, and cholera.

The International Medical Congress.—Already twenty-three foreign governments have signified their intention of being represented. Eighty-eight foreign societies are already enrolled, and over three thousand medical men have signified their intention of being present. So that it is estimated that there will be at least six thousand members. Virchow, Charcot, Brouardel, and Nothnage are among those expected.

Dr. E. P. Baker died in Aurora, Cayuga Co., N. Y., June 4, 1893, aged seventy-four. Dr. Baker was graduated at the old Geneva Medical College about the year 1843. His professional life was spent in Cayuga County, and for the last twenty-three years he practised in Aurora, and was physician to Well's College and to the Aurora Academy and Military School. He was a man of singularly gentle and lovable nature, conscientiously devoted to his duties, of high and honorable aims, incapable of subterfuge. He is sincerely mourned by the profession, and the community in which he labored so long.

Report on Cholera.—Dr. W. A. Wheeler, Chief of the Medical Bureau at Ellis Island, who has been for several months investigating the sanitary condition of the

principal European ports from which the United States receive immigrants, came home recently. He states that there is little probability of cholera being introduced into this country, even should it break out again in epidemic form in Europe. The doctor says that in Bremen and Hamburg emigrants bound for American ports are kept under observation, after being washed and having their clothing and baggage fumigated, until the period for the development of the disease has passed. In regard to the appearance of cholera in Naples within the last few days, the doctor said: "I believe it was imported, and I have no doubt that under the present good sanitary arrangements of the city it will be checked." The steamship companies with lines running to Hamburg and Bremen were ably co operating with the German Government and the American consuls to prevent the introduction of cholera through immigrants from Russia. Nearly all the cases of cholera reported this year have been of a sporadic sort. There were several recently in Marseilles. There was a chance of the disease being brought hither in rags, but that has been reduced to a bare possibility by thorough disinfection. Russian Jews, the doctor said, had had trouble getting passage from Hamburg to America, and they were flocking to Rotterdam and Antwerp, where there seems to be less care in the selection of steerage passengers by the steamship companies.

The disease has appeared in Naples within the past ten days. On July 19th Dr. Young, of the Marine Hospital Service, who is stationed at Naples, cabled to Surgeon-General Wyman that four fatal cases had occurred there, and on July 25th sent another despatch saying that the disease still prevailed, and that the condition was growing worse. A large number of emigrants were preparing to sail for America, but owing to the action of the authorities they could not be properly inspected. The Surgeon-General has forwarded instructions to refuse bills of health unless all the regulations in regard to isolation and detention of suspected cases are complied with. The authorities of Naples deny that the disease is true Asiatic cholera, but Dr. Young says that the cholera bacillus has been found in all the cases examined. The disease has also broken out in St. Louis, at the mouth of the Senegal River, the capital of the French possessions in Senegambia, West Africa. The deaths have already reached an average of fifty daily, and a genuine panic prevails among the inhabitants. The disease is spreading among the European residents, three of whom have died. The population of St. Louis is about twenty-eight thousand, of which number about twelve thousand live in the suburbs of the town.

The Spanish Government has set a good example to the authorities in other European countries by instituting a prosecution against the Mayor of Palafurgel, a small town near the Mediterranean, for concealing the existence of a few cases of cholera. Dr. Haffkine is now in India making experiments to determine the efficacy of inoculation in the prevention of cholera. The authorities are offering him every facility for prosecuting his researches. He has already inoculated over two hundred persons at Simla for cholera, including many medical men, high officials, and ladies. Several native Indian States have taken up his system of inoculation, and it is used at Agra, Delhi, and Lucknow. In one British regiment over four hundred men have been inoculated.

Dr. Egbert Guernsey, Jr., died on July 25th, at Fishkill-on-the-Hudson, from pulmonary hemorrhage. He had been ill for some time, and was living at his father's country residence. He was thirty-two years old.

The Iowa State Board of Medical Examiners has passed the following resolution in reference to the recogdition of medical colleges:

Whereas, A number of medical colleges in the United States and Canada have adopted and require a four years' graded course of medical lectures as a condition of graduation, and others have expressed the determination to do so; therefore,

Resolved, That after July 4, 1898, no medical college shall be recognized by this Board as "of good standing" within the meaning of Section 1, Chapter 104, Laws 1886, that does not require as a condition of graduation four graded courses of medical lectures of not less than six months each—no two of which said courses shall be within the same calendar year. That graduation from any college of Dentistry, and Veterinary Medicine, or of Pharmacy, upon a satisfactory examination in anatomy, recognized by this Board as of good standing, may be accepted as the equivalent of the first year's course of medical lectures by colleges requiring as a condition of graduation the graded courses above specified.

Visitors to the Pan-American Congress.—Dr. Ernest Hart, Editor of the *British Medical Journal*, and Professor Dr. Czerny, of Heidelberg, will be among the guests of the Pan-American Medical Congress. The latter is booked for the Pan-American excursion to Rome by the Werra.

Official Delegates to the Pan-American Medical Congress.—Practically, all of the Governments have appointed official delegates to the Congress in response to the invitation by the President of the United States. The United States Government will be represented by six delegates. The larger cities of all the Latin-American countries have appointed delegates to participate in the proceedings of the Sections on Hygiene, Climatology, and Demography, and on Marine Hygiene and Quarantine, and similar appointments will be made by the cities of the United States. Seventy six similar delegates have so far been appointed by the Governors of States in the United States. A large number of delegates have been chosen by the medical colleges of the United States and other American countries, to attend the Section on Medical Pedagogics, under the Presidency of Professor J. Collins Warren, of Boston.

A Section on Materia Medica and Pharmacology has been organized under the Executive Presidency of Professor Joseph P. Remington, of Longport, N. J., with Professor F. G. Ryan, 3739 Brown Street, Philadelphia, as English-speaking Secretary. The work of this Section promises to be very interesting. Delegates have been invited from the pharmaceutical societies and colleges in all the Americas. Those contemplating the preparation of papers on pharmaceutical topics, are requested to send the titles at once to the Secretary.

At the Beginning of the Present Year there were no less than two hundred and ten medical journals published regularly in Paris.

Society Reports.

AMERICAN OTOLOGICAL SOCIETY.

Twenty-sixth Annual Meeting, held at the Fort Griswold House, New London, Conn., July 18, 1893.

MORNING SESSION.

THE Society was called to order by the President, Dr. Gorham Bacon, of New York.

The Comparative Anatomy of the Ossicles.—The first paper was one with this title, read by DR. LUCIEN HOWE, of Buffalo, N. Y. As comparative anatomy frequently gives important hints concerning the function of different portions of our bodies, the author had examined various works on comparative anatomy for facts in regard to the ossicles in various animals. Finding that very little had been done in this direction, he had made some effort to obtain the ossicles from animals of widely different species. Attention was called to the following peculiarities, which had been noted in these observations:

1st. As to the processus longus of the malleus, concerning which there is some difference of opinion. Gruber has described this process as bony in early life, considering that later it degenerates into connective tissue, and is then to be regarded as a ligament. A study of comparative anatomy appears to indicate that this is the true view, for in one or two we find the long process persisting as a true bone.

2d. Concerning the malleo-incudal joint. Helmholtz has described this joint with much detail, and holds that in the human being rotation in one direction is practically unlimited, while in the other direction it is suddenly arrested. These observations have been verified by the author in the orang and some of the higher air-breathing animals.

3d. It is worthy of note that the form of the hammer and anvil differ very greatly not only in different genera, but also in individuals of nearly allied families. On the other hand, the stapes is remarkable in having almost always a certain approach to the stirrup form.

The author presented these observations on account of their possible intrinsic interest, and also with the hope that future observations may throw light on certain obscure questions regarding the physiology and pathology of the bones of the middle ear.

The Strongly Counter-irritant Effects of the Usual Mastoid Operation, was the title of a paper read by DR. ALBERT H. BUCK, of New York. (See p. 129.)

DR. SAMUEL THEOBALD, of Baltimore, said that the view of Dr. Buck was borne out by many cases in which the mastoid is opened and no pus found, and in which pus does not subsequently make its appearance, but yet the case is greatly benefited by operation. These cases sustain the view that much of the benefit is due to the counter-irritant effect.

DR. H. KNAPP, of New York, did not clearly understand what was meant by the revulsive or counter-irritant effect of the operation. In many cases there is simply a congestive mastoiditis. At the operation nothing but blood is found, but the result is almost always satisfactory.

In regard to the extension of the suppurative process to the brain, the speaker believed that when we destroy the source of the suppuration we act beneficially upon the extension of it. He thought that in many cases when the mastoid was opened, the cranial cavity opened, and the lateral sinus and jugular vein explored, a great deal of the good effect might have been obtained by simple opening of the mastoid without such extensive operation, especially if there is no great septic condition.

Extensive Caries and Necrosis of the Temporal Bone of a Child.—Mastoid Operation.—Death from Exhaustion and Hemorrhage.—DR. HERMAN KNAPP, of New York, read the paper. The patient, a feeble, anæmic child, came under observation April 28, 1893. For a few months there had been copious and offensive otorrhœa of the left side. The mastoid region was swollen and soft, but no fluctuation was present. May 1st the mastoid was exposed; there was no sub-peritoneal collection of pus. The outer table of the mastoid was removed, with the exposure of a large cavity filled with necrosed bone and granulations bathed in pus. This was removed and the cavity packed with corrosive sublimate gauze. The child improved to some extent, but there was no tendency to repair. Some time later, and a week before death, the probe revealed that the posterior wall of the bony portion of the external ear canal had begun to loosen itself, but it was too firmly attached to permit extraction. On July 3d the ear was carefully probed. This was followed by escape of some dark blood, as had occurred at previous examinations. The wound was dressed and the child went home. During the night there was a continuance of the bleeding, and the child died the following morning. It was impossible to obtain an autopsy. The amount of blood lost did not seem great enough to have caused death; but in the precarious condition of the child it may have hastened the fatal result.

A Case of Chronic Middle-ear Suppuration, with Grave Brain and Lung Complications.—Opening of the Mastoid and Wounding of Lateral Sinus.—Complete Recovery.—Dr. Knapp, of New York, also reported the following case: On December 22, 1892, Mrs. H——, aged thirty-eight, came under observation, complaining of pain, discharge, and deafness in the left ear. There had been occasional attacks of inflammation during the past year. The upper posterior part of the drum membrane was red and bulging, and there was a large perforation in the lower part. There was also catarrhal rhinitis. Appropriate treatment was advised, and during the next three months the condition fluctuated considerably. On three occasions the condition became so aggravated that exploratory operation was decided on; but on each occasion sudden improvement occurred and operation was not done.

March 27th.—The disease took a more serious turn. There was pain in the head, and swelling and tenderness of the mastoid, and pain on percussion about two inches back of the ear. Operation on mastoid was advised, but delayed at the request of the patient on account of the advent of menstruation.

April 13th.—There was severe pain in the head, delirium, with chill and vomiting, and complaint of discomfort in the chest. Pulse, 120; respiration, 30; temperature, 104° F. There was no discharge from the ear. The mastoid was red and tender. The optic disc was hyperæmic and swollen. There were no physical signs of involvement of the lung. The possibility of the lung complication being due to the ear disease, led to operation on the mastoid. No pus or diseased bone was found. The bone was softer and more vascular the deeper the operation went. Chiselling still deeper, there was a sudden gush of dark blood. This ceased after a minute's pressure, and the cavity was packed with corrosive sublimate gauze. The ear showed no reaction, but for a week the patient was in a critical condition from the lung complication, which was declared to be a pleuro-pneumonia. From the ninth day after operation the patient improved steadily and made a complete recovery. In reviewing the case, it was thought that the otic disease was the origin of the difficulty, and that the inflammation passed into the skull through the roof of the drum cavity.

DR. J. ORNE GREEN, of Boston, thought that in some cases where hemorrhage is attributed to opening of the lateral sinus the blood does not come from that source. He had had two cases in which he satisfied himself that the free escape of blood did not come from the lateral sinus. A probe demonstrated a cavity with complete bony wall. The great hemorrhage in these two cases was attributed to the opening of a large diploic vein.

Autopsies in Two Cases of Complicated Middle-ear Disease.—DR. T. Y. SUTPHEN, of Newark, N. J., reported the following cases:

Case I.—Man, aged thirty, had immense abscess involving the left mastoid region. This was opened. There was a long history of middle-ear suppuration. Two days later, when the author first saw the case, the mastoid was found extensively carious. During the next few days the patient became worse, with development of cough, elevated temperature, and dulness over right side of chest. In a week he died in coma.

Autopsy showed an abscess canal outside of dura mater, extending to the cerebellum, where it penetrated the dura and ended in abscess in the brain tissue, having adjacent to it other spots of softened tissue. There were also the lesions of a septic pleuro-pneumonia.

Case II.—Case of right middle-ear inflammation lasting several weeks. For ten days there had been severe headache on the right side. No swelling or tenderness over mastoid. No paralysis. Three days later the patient became comatose, with temperature of 104° F. The following day the mastoid was opened, but no pus was found. The patient died the next morning.

The autopsy showed no communication between the mastoid and the cranial cavity. The meningeal space contained a quantity of sero purulent fluid. The right lateral sinus contained a large softened clot communicating with the meningeal cavity. The entire meningeal surface of the cerebellum was bathed in pus. No abscess was found in the brain substance.

Fatal Thrombosis of the Lateral Sinus, with Autopsy.—Dr. Emil Gruening, of New York, reported the case of a woman, aged thirty-eight, who had had occasional discharge from the left ear for six years. Two months before coming for treatment profuse discharge set in and continued. There were two perforations in the drum membrane, and the mastoid region was red, swollen, and œdematous. The ordinary mastoid operation was done, and pus and granulation tissue found. The lateral sinus was exposed, but it did not pulsate. Four days later pyæmic symptoms manifested themselves, with marked and sudden variations in temperature. There were also evidences of lobar pneumonia. The patient died, and autopsy revealed pneumonia and thrombosis of the lateral sinus.

The Statistics of the Aural Department of the Massachusetts Eye and Ear Infirmary were presented by Dr. Clarence J. Blake, of Boston. They were for the three months, April, May, and June, 1893. The total number of patients seen during this time was 7,685. Of this number 1,414 were new patients. The cases were classified in tabular form, according to the disease present, under the following heads: 1. Morbi auris externæ; 2, morbi auris mediæ; 3, morbi labyrinthi et acustici; 4, morbi nasi et naso-pharyngis, and morbi et operationes. The total number of operations done was 208.

Detailed reports of a number of the more interesting cases were given.

AFTERNOON SESSION.

Dr. J. Orne Green, of Boston, exhibited a large number of pathological specimens of ear disease, and gave reports of the cases.

Stapedectomy and Other Middle-Ear Operations was the title of a paper by Dr. Clarence J. Blake, of Boston. During the past year the author had investigated the question of the possibility and advisability of the extraction of the stapes in chronic non-suppurative disease of the middle ear. As a result of the investigation the following conclusions seemed justified: That in those cases of non-suppurative disease of the middle ear, with a high degree of deafness, the operation of stapedectomy is most likely to be futile, because of the degree of fixation of the base of the stapes leading to fracture of the crura in the attempts at removal.

That in the class of cases where stapedectomy has apparently given the best results, viz., fixation of the stapes as a sequence of chronic suppurative disease, it is by no means certain that equally good results could not have been obtained by surgical mobilization and subsequent care.

That while removal of the stapes is by no means so hazardous a procedure, it still opens up the possibility of interference to an unknown degree with the most important part of the organ of hearing, and an almost equally important peripheral organ of equilibrium.

In order that the operator might, in the non-suppurative cases, avail himself of the co-operation of the patient, and apply, in the progress of the operation, a series of hearing tests to determine the location of the principal obstacle to sound transmission, and determine the extent to which surgical interference was advisable, the plan of "exploratory tympanotomy" was devised. The speaker prefers, when possible, in cases of non-suppurative disease of the middle ear, to begin with exploratory tympanotomy, which is an operation without general anæsthesia, leaving it to be determined by the examination and tests made during the operation as to whether the stapes can or shall be removed or not. In suppurative cases he prefers first doing synæchtomy, tenotomy, and crural circumcision, with, if necessary, the additional application of an artificial drum, allowing a proper time limit for the determination of the effectiveness of these procedures before submitting the patient to the final operation of stapedectomy.

Observations on the Removal of the Stapes.—Dr. Frederick L. Jack, of Boston, presented a paper supplementary to one he had read at the last annual meeting. Since bringing the matter before the Society last year, the operation had been tried in thirty-two additional cases. These, with the sixteen previously reported, furnish forty-eight cases for observation and study. In reviewing the cases there is much to encourage the adoption of the procedure, but its clinical application will require modification.

The following conclusions were presented:

1. The operation is followed by the best results in the class of cases where, from the increase of time, the effects of suppuration, or hypertrophic inflammation, the stapes offers an obstruction to sound waves; by its removal the hearing is improved. The results in cases of otitis media chronica insidiosa, on account of failure to extract the foot-plate, are not encouraging.

2. Inflammatory reaction is unusual, and followed by no bad results.

3. The hearing is not necessarily impaired by the subsequent growth of a thin cicatricial membrane over the fenestral niche.

4. Some cases of tinnitus and aural vertigo are relieved, and there is little chance of causing permanent vertigo in cases where it had not previously existed.

5. It rarely happens that a patient improves for all tones. Improvement in hearing the human voice was out of proportion to the improvement for other sounds, and the reverse sometimes occurred.

6. Failure of success in some cases may be due to hemorrhage into the labyrinth at the time of the operation. It is believed to be a rare complication, but was thought to have occurred in one or two cases.

7. In removing the various ossicles, the stapes, if found diseased, should also be removed.

The Surgical Treatment of So-called Ménière's Disease (Aural Vertigo).—Dr. C. H. Burnett, of Philadelphia, maintained that the name, "Ménière's Disease," is inaccurate and unjust. It is inaccurate, because it is indiscriminately applied to all forms of aural vertigo, regardless of the seat of the otic lesion; whereas Ménière attempted to prove the existence of a disease of the semicircular canals as the only cause of aural vertigo—an entirely untenable hypothesis.

The name is unjust, because Flourens in 1822, and Deleau in 1836, described aural vertigo more accurately than Ménière in 1861, and Deleau came much nearer than any previous observer to the solution of the origin of aural vertigo in placing the cause in lesions of the middle ear. Ménière's observation of a case of aural

vertigo, in which, owing to the sudden death of the patient, he is said to have made a post-mortem examination of the temporal bone, revealed nothing more than any roughly- and rapidly-made dissection of this bone would do—viz., pinkish serum in the semi-circular canals. It proved absolutely nothing as to the cause of aural vertigo observed before death, and has led to great confusion in diagnosis and error in treatment of ear-vertigo. In fact, there is no such phenomenon as "Ménière's Disease," as commonly spoken of by the general profession.

Aural vertigo, on the other hand, due to lesions in the middle ear, is of very frequent occurrence. It is often not recognized, especially by the general practitioner, as aural vertigo, nor even as the so-called Ménière's disease, in which, to say the least, the cause of the vertigo is placed in the auditory apparatus. It is not unusual for aural vertigo to be attributed to intestinal disturbance, or to neurasthenia, instead of to an aural lesion. Hence, the diagnosis being erroneous at the outset, the treatment is wrong and the patients do not recover.

True aural vertigo, due to a lesion in the middle ear, chiefly from chronic catarrh of the tympanic cavity, is paroxysmal in character, and attended with tinnitus and deafness in the affected ear. It is caused by the inward pressure exerted upon the labyrinth-fluid by the retracted and ankylosed ossicles. The foot-plate of the stapes is thus unduly pressed into the oval window and there held by the above-named forces, paroxysmally and for longer or shorter periods.

The treatment consists in removing the retractive force and liberating the stapes, preferably done by the surgical removal of the incus. This bonelet, the incus, which in its relation to the other two auditory ossicles may be likened to a keystone in an arch, when removed, destroys the so-called arch, and the retractive and impacting power of the malleus can never again be exerted upon the stapes. This liberates the stapes, which furthermore is now pulled outward by the stapedius muscle, relieved of the antagonism of the tensor tympani.

Regarding the removal of the stapes from the oval window, it may be said that it does not seem that this operation is necessary for the relief of deafness or of aural vertigo, according to Dr. Burnett's experience. Liberation of the stapes, and not its entire removal, is all that is necessary in most cases. If the stapes be the "key to the situation," as it may indeed be, it seems wise to leave the key in the key-hole—the oval window.

That it is the liberation of the stapes in the oval window that effects the cure in aural vertigo, would seem to have been demonstrated by a case reported by Dr. Burnett in 1888, at which time the explanation of the *modus operandi* in such cases was suggested by him.

Notes of several cases in which tinnitus aurium and aural vertigo had been entirely cured by the surgical removal of one or more of the auditory ossicles, were recorded in the paper.

On the Difficulty of Operation in the Depths of the Ear Canal.—Dr. Robert Barclay, of St. Louis, read a paper with this title, and presented a description and drawing of new instruments for surmounting the difficulty. Deep operations within the ear have recently been found to have a much wider application than was previously supposed. The indications for such operations have already been formulated, and their technique already elaborated by Drs. Sexton, Burnett, Blake, and Jack. The problem which still remains unsolved is how to overcome the difficulties attending the performance of these operations. The difficulty is in large part due to the peculiar conformation of existent instruments—specula and shafts of blades. To obviate the objections belonging to the ordinary aural specula, the writer's new speculum for operations has been designed. This consists of two parts—a tube and a handle. The tube represents the inner portion of the ordinary speculum divided obliquely at two-fifths its distance from the outer rim. The handle is detachable and is made in three forms: like a spoon-handle, fixed to the tube dipper-shaped; like an imperfect ring, or like a split tailors' thimble. By means of the handle, the instrument is held in place by the finger or thumb, the rest of the hand being free. By dispensing with that portion of the speculum that projects beyond the intertragal notch of the ear, this instrument allows a hand rest for steadiness, and a maximum of shortening and of movement of instruments in operations within the ear.

Cases were cited where difficult, delicate, and dangerous operations had been done through this speculum. One was that of a large exostosis one half inch thick, lying within an eighth of an inch of the drum-head, which was removed, the drum-head escaping all injury. Another, that of an artificial auditory canal, one-quarter of an inch in diameter, bored through a complete bony septum five-eighths of an inch thick.

The necessity for the most delicate and accurate manipulation of instruments in operations upon the deeper parts of the ear, and the difficulty of satisfying it with instruments having the shaft and handle of existent patterns straight, once bent, or twice bent, with extremities parallel, had led the author to devise a shaft and handle so proportioned as to combine the desirable features of those already in use, without their defects. The essential features of the instrument are that the aluminium handle is of dimensions and weight most favorable to delicate and accurate manipulation; it is twice bent, the long axis of the handle passing directly through the operative extremity of the operating shaft. The lateral shaft, joining the handle to the operating shaft, is of length only sufficient to permit the greatest illumination and vision along and beyond the operating shaft. The operating shaft is of the smallest dimensions possible, and is at right angles to the lateral shaft.

The instrument is made in two forms. In one the handle and shaft are in one piece, in the other, the instrument is in two parts and separable, and interchangeable blades of such extremities as may be desired may be secured to the handle.

The author expressed the hope that those improvements will be of aid to inventors, and also stimulate research in this field of aural surgery, while rendering more generally available the resources in the operations designed by Drs. Sexton, Burnett, Blake, and Jack.

Aural Reflex of Unusual Character Due to Impacted Cerumen.—Dr. Samuel Theobald, of Baltimore, related the case of a woman about forty-two years of age, the mother of a large family and of a non-nervous temperament, who had suffered for six months with an annoying cough and with spells of inability to swallow food. These symptoms increased in severity, and it was noticed that any manipulation of the right ear brought on the attack. A plug of cerumen, which probably had been forced down upon the tympanic membrane by unsuccessful attempts to remove it, was discovered in the right ear. It was removed by syringing, and all the unpleasant symptoms at once disappeared. Ear-cough is, of course, of not infrequent occurrence, but spells of inability to swallow due to reflex aural irritation are rare. Burnett, in his work upon the ear, states that both Senac and Jissot have described cases of this character.

The Statistics of Ear Disease.—Dr. B. Alex. Randall, of Philadelphia, presented a tabulation of the five thousand cases of his past four years' work in illustration of some points of the statistical reports of practice, the nomenclature being practically that offered by Dr. Spear, and the grouping into columns, giving the ear affected, the sex of the patient, and whether adult or child. In its explanation, he urged the report according both to diseases and individuals, with such subdivisions as given, and that the attempt should be made to give the therapeutic results, as being a good aid to progress in treatment. The more elaborate the report made, the more it would compel fulness and accuracy of record, and thereby prove increasingly instructive to the practitioner himself as well as others.

Dr. Gorham Bacon, of New York, exhibited a new form of incus hook devised by his assistant, Dr. Hewit.

A paper entitled "A Contribution to the Brain Surgery of Ear Disease," by Dr. Thomas R. Pooley, of New York, was read by title.

The following gentlemen were elected to membership: Dr. Eduard B. Dench, of New York; Dr. William Cowen, of New York; Dr. John L. Adams, of New York; Dr. Eduard Fridenberg, of New York; Dr. W. H. Wilmer, of Washington, D. C.

Election of Officers.—The officers for the ensuing year are: *President*, Dr. Gorham Bacon, of New York; *Vice-President*, Dr. Arthur Mathewson, of New York; *Secretary* and *Treasurer*, Dr. J. J. B. Vermyne, of New Bedford, Mass.

The Society then adjourned.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 10, 1893.

H. P. Loomis, M.D., President, in the Chair.

Accessory Liver and Pancreas.—Dr. J. S. Thacher, showed a pancreas completely encircling the duodenum, and causing slight stricture of its canal. Just above the duodenum was an accessory pancreas, a specimen of which was shown under the microscope. Dr. Thacher also presented an accessory liver, two inches in diameter and one-fourth of an inch in thickness, which had been found by Dr. G. A. Tuttle at an autopsy. It was situated on the surface of the spleen and intimately attached to it, and was entirely disconnected from the liver. Microscopical examination showed typical liver tissue.

Dr. T. M. Prudden remarked that he had seen, during the past winter, an accessory pancreas situated in the lesser omentum.

Dr. George P. Biggs said that he had found an accessory pancreas situated in the muscular and submucous coats of the duodenum, about one-half inch from the pylorus.

Pachymeningitis Hemorrhagica Interna—Intercurrent Diseases in General Paresis.—Dr. E. D. Fisher presented microscopical specimens showing pachymeningitis hemorrhagica interna. They were taken from a negro, forty years of age, who was suffering from general paresis. There was an old tubercular cavity in one lung. The speaker said that he desired to call attention to the case, 1, because it is generally stated that general paresis is comparatively rare among negroes and Irish; and 2, because it showed the insidious way in which acute intercurrent diseases develop in general paretics. As a matter of fact, general paresis is as common among the two races mentioned as among others, provided their surroundings and mode of life are favorable for its development. Acute intercurrent diseases also change the course of the mental trouble, the mental symptoms returning after the subsidence of the acute disease. It should be an invariable rule to make a careful physical examination of the heart, lungs, and other organs in such subjects.

Primary Carcinoma of the Liver, with Multiple Secondary Deposits.—Dr. George P. Biggs presented a liver containing multiple new growths. It had been removed from a man, forty-two years of age, who was admitted to the hospital late one evening, and who died before morning. As a consequence a complete history was not taken, and only a hurried physical examination was made. He had had pain in the right side for three or four months, and had been steadily emaciating, but there had been no gastric symptoms, and he was only slightly jaundiced. A nodulated tumor could be very distinctly felt in the abdomen, filling nearly its entire cavity, and on auscultation there was distinct friction over the tumor. A diagnosis was made of carcinoma of the liver. At the autopsy the tumor was found to be an enlarged liver, the lower end of the right lobe being in the right iliac fossa, and the fissure between the two lobes being situated considerably to the left of the median line. The organ measured 29 ctm. vertically, 31 ctm. transversely, and 12 ctm. in thickness, in the upper portion of the right lobe. Its weight was twelve pounds twelve ounces. The liver was everywhere studded with innumerable growths, yellowish, greenish, or white in color in the fresh state, and varying in size from a pin-head to a hen's egg. A careful search for a new growth to explain the condition found in the liver resulted only in finding three lymphatic glands at the transverse fissure, which were about 1½ ctm. in diameter, and evidently contained tumor tissue. About two inches below the lower end of the right lobe of the liver was a circular scirrhous growth, about 7 ctm. in diameter, which was evidently the oldest growth in the liver. The specimen exhibited under the microscope showed the new growths to be carcinomata. The large growth referred to was probably the primary one, and the secondary deposits were probably disseminated through the liver through the medium of the biliary passages.

Primary carcinoma of the liver is very rare, but is spoken of in three forms, viz.: 1, A single nodule, usually in the right lobe; 2, a diffuse infiltration of the whole liver; and 3, small nodules along the course of the portal vein. No mention is made in the first variety of the existence of secondary deposits.

Syphilitic Deposits in Liver and Lung—Cerebro-spinal Meningitis.—Dr. Biggs next presented the liver and lungs removed from a man who died of cerebro-spinal meningitis. There were numerous adhesions over the surface of the liver, a large number of cicatrices, and a general increase in the fibrous tissue, with considerable fatty change. The left lung showed a peculiar increase in the fibrous tissue throughout the lower two-thirds of the lower lobe, and also through a portion of the upper lobe, so that in the fresh state it felt almost solid. The fibrous tissue was very tough; there was no crepitation, and practically no aëration of this portion of the lung. There were no cicatricial bands on the surface. The opposite lung presented the same general appearance.

The brain and a portion of the spinal cord from the same patient were also exhibited. They were chiefly of interest on account of the very extensive involvement of the choroid plexuses. The exudation over the base was very thick, while there was scarcely any on the convexity. The lateral ventricles were both distended with purulent fluid, and a similar fluid was found in the fourth ventricle. The same abundant exudation which was found on the choroid plexuses also extended down the whole spinal cord. The patient lived twelve days after developing symptoms of cerebro-spinal meningitis, and during all this time the disease was very active. This may explain the abundance of the exudation. The speaker said that out of ten recent cases, this was only the second in which the exudation had been so especially marked over the base as compared with the convexity.

Diphtheritic Vaginitis.—Dr. Biggs also presented a specimen of extensive diphtheritic vaginitis. The patient was admitted to Bellevue Hospital with the statement from her attending physician that she was suffering from alcoholic neuritis. This diagnosis was confirmed. On the third day after admission the nurse noticed an offensive vaginal discharge, and examination showed the vagina to be the seat of a diphtheritic inflammation. Her temperature on admission was 99° F. in the morning and 104° F. in the evening, and this continued for six days, when the evening temperature rose to 105° F. For about twenty-four hours before death she had had a profuse diarrhœa. The woman was not in a condition to give a reliable history. Her friends stated that she was a married woman, and that she had been sick for about three weeks previous to going to the hospital. The case was peculiarly interesting in view of the fact that the uterus and appendages were perfectly normal. The entire vagina was covered by a very marked yellowish diphtheritic membrane, but there was no ulceration or stripping off of the membrane. It was limited above by the internal os. She was under observation for eleven days, but nothing abnormal was observed about the throat. At the autopsy it was found that the lower part

of the rectum was the seat of a recent diphtheritic inflammation. There was also a fairly advanced tuberculosis of one lung and a slight chronic diffuse nephritis.

A Case of Cerebro spinal Meningitis, with Strange Urinary Symptoms.—Dr. Herman M. Biggs presented specimens from a case of cerebro-spinal meningitis which was admitted to his ward on the night of May 3d. The patient did not feel ill until noon of that day, then he rapidly became delirious, and at midnight was admitted to the hospital in a comatose condition, and had a temperature of 104° F. The temperature varied between 103° and 106° F., up to the morning of May 7th, when he died. The first specimen of urine was examined on the day following his admission, and it was found to contain a good deal of blood, which, on standing, readily subsided to the bottom of the vessel. The clear portion contained considerable sugar. The next day there was apparently a much larger quantity of blood in the urine, but intimately mingled with it. Microscopical examination, however, showed only a comparatively small number of red blood-corpuscles. The urine no longer contained sugar. He continued to excrete a considerable quantity of urine of this character up to the time of his death. At the autopsy his bladder was found distended, the wall thickened, and the mucous membrane the seat of innumerable hemorrhages, and of some superficial erosions. In some places there was a delicate deposit of fibrin on the surface. The process had apparently extended up one ureter and involved the pelvis of that kidney, while the urine in the pelvis of the other kidney was perfectly clear and free from blood. The other lesions were those of cerebro-spinal meningitis, there being an extensive deposit over the base of the brain, and the posterior surface of the spinal cord, chiefly, however, in its lower portion.

The clinical history of this case would lead one to believe there was in addition to the glycosuria, which is occasionally found with cerebro-spinal meningitis, a hæmoglobinuria, but the absence of blood or blood-coloring matter from the urine found in one kidney at the autopsy would seem to exclude hæmoglobinuria, and the condition of the bladder would indicate that this organ was the source of the hemorrhage. A few petechial hemorrhages were found in the pleura, and in several places where the skin had been abraded there was a marked tendency to hemorrhage.

Lympho-sarcoma of the Retro-peritoneal Glands, Mesentery, and Intestine.—Dr. H. M. Biggs also presented specimens from a case of lympho-sarcoma. The patient's statements were found not to be reliable, but as nearly as could be ascertained he was perfectly well up to last January, at which time he took some medicine for worms which produced a very profuse catharsis. Soon after this his abdomen became distended and tender, his bowels constipated, and he suffered considerably from colicky pain. On admission he was jaundiced, the abdomen was distended and tympanitic, but not very tender, and the abdominal wall on the right side was thick and hard, and several small nodules could be felt in the substance of the wall at its lower portion. His temperature rarely rose above 100° F. High enemata, saline cathartics, and other similar measures failed to open his bowels, and after being in the hospital for one week it was thought advisable to do an exploratory laparotomy. On opening the abdomen the peritoneum everywhere was found to be intensely injected, and the abdominal wall enormously thickened and the seat of a new growth. Near the junction of the jejunum and ileum, and also at a point higher up, new growths were found, and the retro peritoneal glands and mesentery were similarly involved. Further operative measures were therefore abandoned. The patient died on the following day. Microscopical examination of sections from one of the masses found in the intestinal wall, and from the retro-peritoneal glands, showed the new growth to be a lympho-sarcoma, which apparently began in the retro-peritoneal glands and extended thence to the mesentery and intestinal wall. It involved the mucous membrane and submucous tissue, and also slightly the muscular tissue of the gut.

Dr. J. S. Thacher recalled a similar case he had seen, in which there was extensive infiltration of the mesentery and of the intestine near the head of the pancreas, but which did not involve the pancreas.

Arthritis of the Knee.—Dr. Thomas H. Manley exhibited a knee-joint which had been removed from a young woman. She had a good family history, and denied having had gout, rheumatism, or syphilis. On January 12th she contracted a severe cold, and two days later first began to have pain about the left knee-joint. On February 1st it was swollen and acutely inflamed, and her attending physician thought she was suffering from acute articular rheumatism. On March 27th she was admitted to the Harlem Hospital, and at that time had a pulse of 108, and a temperature of 101° F., and a physical examination showed a slight consolidation at the apex of the left lung. She was profoundly anæmic and prostrated, and her general condition was such that a serious operation was considered unadvisable. There was a small fistula at the inner side of and below the knee, and evidence of insufficient drainage, so better drainage was secured, but without resulting in relieving the pain or in any general improvement. Her condition became steadily worse, and finally was so critical that it was decided to amputate the limb. The operation was done on April 19th. Before the operation her pulse was 160, respirations, 44, and temperature, 105° F., yet on the following day her temperature had fallen to normal, and from that time on she rapidly improved. The case was considered at first to be one of tubercular disease of the knee, but he had learned subsequently that the patient had been quite dissipated, and that there was some reason for believing that she may have had a gonorrhœal arthritis. The speaker also briefly alluded to a case of arthritis of the wrist which developed shortly after confinement. Here the child had gonorrhœal ophthalmia, and the husband admitted having had gonorrhœa six weeks before the confinement.

Dr. R. H. Sayre said that from a cursory examination of the specimen, without making a section of the bone, he would look upon the case as one of purulent arthritis. There was apparently no evidence of tuberculosis. He thought if the joint had been opened thoroughly and cleaned out at an earlier stage amputation might have been avoided.

The specimen was referred to the Microscopical Committee for examination.

Tubercular Empyema — Amyloid Degeneration — Acute Miliary Tuberculosis.—Dr. F. Ferguson presented gross and microscopical specimens of amyloid degeneration. The microscopical specimens were prepared by immersion in a 1,500 watery solution of the dahlia stain, then thoroughly washing in water, and mounting in a very weak solution of acetate of potash. The liver from this case was very much enlarged, and an examination of some frozen sections of it showed apparently, in addition to the amyloid degeneration, a few tubercles. The kidneys showed a few tubercles and amyloid degeneration, which in the cortex was confined almost entirely to the arteries and in the pyramids to the tubes. There was a history of some thoracic trouble having existed for nine months, and at the autopsy there was found to be a tubercular empyema, and also a tubercular peritonitis.

Extensive Cerebral Hemorrhage—Cardiac Hypertrophy without Dilatation.—Dr. Ferguson also presented specimens from a case of extensive cerebral hemorrhage. The man was brought to the hospital about ten hours before death. He had a slow and strong heart action; tremor, more marked on the right side, and shortly before his death he had Cheyne-Stokes respiration, and one severe convulsion. A diagnosis was made of apoplexy. An examination of the brain showed the hemorrhage to be unusually extensive; the septum lucidum had been destroyed; the third and fourth ventricles were filled with blood, and the hemorrhage had made its way to the surface, so that at first it looked as though there

had been a meningeal hemorrhage. The convolutions were much compressed. The vessels at the base of the brain showed well-marked atheroma. The vessels of the kidneys were the seat of endarteritis obliterans. The heart was hypertrophied, but there was not that marked dilatation of the ventricles so commonly found in connection with chronic renal disease. There were no valvular lesions, and the heart muscle was in good condition.

Dr. Ferguson also exhibited specimens which had been removed from an Italian, twenty-two years of age. No history was obtainable except that there had been a moderate elevation of temperature and extreme dyspnœa. An examination of the heart, post-mortem, showed the mitral orifice contracted to a little less than half an inch, and also sufficient contraction of the segments of the aortic valve to interfere with their proper action. There was also a typical nutmeg liver, and the lungs showed the typical appearance described by Delafield as "the pneumonia of heart disease."

The Society then went into executive session.

Stated Meeting, May 24, 1893.

H. P. Loomis, M.D., President, in the Chair.

Sarcoma of the Uterus and Ovary.—Dr. George C. Freeborn presented a series of specimens illustrating sarcoma of the uterus and of the ovary. The first specimen, one of sarcoma of the uterus, was removed by suprapubic hysterectomy, by Dr. Bache Emmet, from a woman, thirty-four years of age. She had had six children, and had been perfectly well up to two years before. At that time she had a miscarriage, and since then had flowed freely and continuously. The specimen measured 12½ ctm. long and 7 ctm. transversely between the horns. Growing from the fundus of the organ was a soft, fungoid mass, and projecting from the right side of the uterine body was an oval mass 2 ctm. by 11 ctm. A latero-perpendicular section through the uterus showed the fundus occupied by a crescentic-shaped zone, 2 ctm. in thickness, made up of roundish masses, reddish in color, embedded in soft, white tissue. Leading from the right side of this zone to the external surface was a triangular cavity filled with shreds of necrotic material. The mucous membrane was almost entirely replaced by a zone of tissue composed of red and white nodules of soft consistency, many of which formed papillary projections into the uterine cavity. Microscopical examination showed the zone at the fundus and the mass to the right to be a round-cell sarcoma, containing some small spindle-cells, and showing necrotic changes. The mucous membrane was replaced by a new growth of round-cell sarcoma, which had infiltrated the muscular tissue to a considerable extent, and the surfaces of the papillary projections were necrotic.

The second specimen, one of sarcoma of the uterus and ovary, was removed post-mortem from a woman, fifty-two years of age, who was in the service of Dr. Hanks at the Woman's Hospital. She had had six children, and the menopause occurred five years previous. At that time she began to have pain in the right side, and her abdomen began to swell. Microscopical examination of the curettings from the uterus showed the presence of a sarcoma. An exploratory laparotomy revealed a retro-peritoneal sarcoma filling the abdominal cavity, and no attempt was made to remove it. The patient died eleven days later, and the autopsy showed general peritonitis and chronic diffuse nephritis. The uterus measured 10 ctm. long by 8 ctm. across the horns, and a sagittal section showed its cavity dilated by an oval mass, 4½ by 6 ctm., growing from the anterior wall. When fresh, this mass was soft, and mottled red and white. The left ovary was atrophied, while the right measured 7 ctm. by 2 ctm., and a transverse section showed the ovaries reduced to a soft, white mass. The mass removed from the omentum was also shown. It was oval, and measured 30 by 16 ctm., and was found occupying the lower portion of the abdominal, and the upper portion of the pelvic, cavity. It was firmly adherent to the lateral walls of these cavities, to the fundus of the uterus, and to the enlarged right ovary. The tumor was attached to the stomach. The whole tumor presented a rough surface, and anteriorly it was studded with numerous small cysts containing grumous blood and necrotic tissue. On longitudinal section its central portion was shown to be occupied by a spherical cyst, 11 ctm. in diameter, having a smooth internal surface, and containing reddish-brown fluid. The posterior wall was thin, and composed of fibrous tissue; the anterior wall was quite thick, and contained various sized red nodules, embedded in white, soft tissue. Microscopical examination showed the mass in the uterus, and the ovary and tube, to consist of small, round-cell sarcoma, containing some spindle cells. The tumor of the omentum was made up of several kinds of sarcoma—small round cell, giant-cell, small and large spindle-cell, and angio-sarcoma.

The next specimen, sent by Dr. C. Cleveland for microscopical examination, was a uterus measuring 14 ctm. in length and 10 ctm. across the horns, and containing an irregular round and spindle-cell sarcoma. The mucous membrane of the uterine cavity, above and below the tumor, showed adenomatous hyperplasia.

The next specimen had been sent by Dr. G. M. Tuttle to the speaker for examination. The smaller ovary showed the mesosalpinx much elongated, and containing a small, thin-walled cyst, and on section it was found to consist of a soft, white mass, enclosed in a thin, fibrous capsule. The surface of the larger ovary showed numerous small cysts, and internally the same soft, white structure, and, in addition, a central necrotic area. The tube was enlarged, and on longitudinal section no lumen could be found. Microscopical examination showed both ovaries and tubes to be sarcomatous, spindle-cells predominating. The patient died on the seventh day after the operation, of what was supposed to be secondary deposits in the lungs. No autopsy was permitted.

The next specimen was a small, spindle-cell sarcoma of the ovary, removed by laparotomy. On section it was found to consist of a soft, white mass, and several cysts enclosed in a moderately thick capsule.

Another sarcoma of the ovary was also exhibited, which had been removed by Dr. Cleveland, by laparotomy, from a woman, twenty years of age. The history of the tumor extended only over a period of three months. The tumor was a bilobed mass, having a smooth surface, and attached to the right horn of the uterus by a flat pedicle about five centimetres wide. On section it was found to consist of soft, white tissue, enclosed in a thin, fibrous capsule. Microscopical examination of frozen sections showed it to be a small, round-cell sarcoma with scanty stroma.

Dr. Freeborn also presented both gross and microscopical specimens from a fibro-cysto-adeno-sarcoma of the ovary. It was removed from a woman, sixty-six years of age, who had given birth to eleven children. The history of the tumor extended over two years, and indicated that growth had been slow except during the last two months. The specimen was a multilocular cyst, two-thirds of which was made up of small cysts with thin walls, the remaining third consisting of a dense, triangular mass, the central portion of which was calcified. The interior of this mass was composed of small cysts with moderately thick walls. The dense mass was found on examination to be a cystic fibro-sarcoma, and the internal cystic mass to be a peculiar form of adeno-sarcoma described by Klebs in "Die Allgemeine Pathologie," Zweiter theil, 1889. p. 748.

Dr. Freeborn said that sarcoma of the uterus and ovary is believed to be rare, and up to the year 1886 Gusserow was only able to collect seventy-three recorded cases of sarcoma of the uterus. Owing to the inaccuracy of the records of tumors of the uterus, the speaker had been unable to bring these statistics down to date. Gusserow's

statistics show that sarcoma of the uterus occurs most frequently between the ages of thirty and fifty, and is quite rare at other periods of life. It occurs most commonly as a diffused growth of the mucous membrane. It may occur as a primary nodule in the walls of the organ, in which case it is of a fibro-sarcomatous nature, but it is exceedingly rare. The statistics of sarcoma of the ovary are equally inaccurate. Up to 1886 Olshausen had collected thirty-seven cases, and Leopold twelve. Of these forty-nine cases the majority were spindle-cell sarcoma, only one case being of the small, round-cell variety. Fifty per cent. of the tumors were bilateral. Many of the recorded cases of fibroma of the ovary, he thought, were undoubtedly spindle cell sarcoma, as this is comparatively common, while fibroma is rare.

Aneurism of the Mitral Valve.—Dr. E. Hodenpyl presented a specimen of aneurism of the mitral valve which had been removed from the cadaver of a middle-aged man who had been treated in the hospital for chronic endocarditis and chronic diffuse nephritis, associated with extreme dropsy. The necropsy showed nothing of interest except the heart. This organ weighed thirty ounces, and on the mitral valve, besides some vegetations, was a small aneurism opening into the auricle.

A Rare Aortic Aneurism.—Dr. Hodenpyl also showed a specimen of aneurism of the aorta, perforating into the pulmonary artery. The specimen was removed from a man, forty-three years of age, a plasterer by occupation. He was treated in the Roosevelt Hospital last year for acute pericarditis, and was admitted the last time on April 29th of the present year. Since last November, dyspnœa and palpitation had been increasingly troublesome, and two weeks prior to admission he began to cough. On admission he was cyanotic, his pulse was 170, irregular and soft, respirations 28, and temperature 102.6°. The urine was acid, had a specific gravity of 1.020, and contained twenty per cent. of albumin. Physical examination of the lungs was negative. There was a pulsation all over the præcordium and in the epigastrium, and the area of præcordial dulness was considerably increased. Coarse, scraping, double murmur was audible all over the præcordium, but was loudest at the base. Here also the rhythm was very irregular, and was increased by deep inspiration. Well-marked præcordial fremitus could be detected all over the præcordium. The heart's action was occasionally irregular. On the day after admission the patient died very suddenly. At the autopsy, clear serum was found in the abdominal, pleural, and pericardial cavities, and all the viscera were intensely congested. Both ventricles of the heart were hypertrophied and dilated; the muscle and valves were normal. Just above the sinus of Valsalva was a small aneurism, which had perforated at its centre by a circular opening having smooth edges, and large enough to admit the tip of the little finger. This opening communicated directly with the pulmonary artery. The other vessels were normal.

Dr. J. H. Huddleston asked if there were signs of pericarditis when the patient was admitted, if there were signs of old inflammation about the aperture, and whether the opening was congenital or of old formation?

Dr. Hodenpyl replied that there were no signs of pericarditis, that the opening could not have been congenital, because the ductus arteriosus was situated higher up, and that the opening must have been an old formation, as there was the record of an old pericarditis, and the murmur had persisted for a long time.

A Single Kidney.—Dr. Hodenpyl also presented a specimen of a single kidney. It had been removed from a man twenty-seven years of age, who, when admitted to the hospital on April 15, 1893, gave a history of having had no movement from the bowels for nine days, during which time there had been a good deal of vomiting and headache, but no abdominal pain. On admission, he was well nourished, face flushed, tongue brown and dry, and tremulous; marked tremor of the hands. Pulse was 76, regular and strong; respirations, 10, temperature, 97.4°. There was complete suppression of urine. The physical examination was negative. On the following day the respirations fell to six, he vomited repeatedly, there was considerable muscular twitching, and troublesome and constant hiccough. The patient was perfectly conscious. He was given an enema, which produced a small fluid stool. He died that evening, and just before death his temperature was 96.4°. The cortex of the kidney was found to be covered with numerous red infarctions which must have interfered with the function of the organ. These infarctions, on microscopical examination, showed signs of degeneration and leucocytic infiltration, but there were no bacteria, nor was there a thrombus of the renal artery. There were no hemorrhagic or petechial spots elsewhere. The cause of the infarctions was obscure. Only one urethral aperture was found in the bladder.

A New Cotton Swab for Obtaining Fluids.—Dr. W. H. Park presented an improved swab for use in obtaining specimens of exudate from the throat for examination. It consists of a thin steel rod, the end of which is wrapped with sterilized cotton, and then placed in a sterilized test-tube closed by a sterilized cotton plug. A finer wire with a smaller piece of cotton might be introduced into wounds, or into the intestine, when it is desired to obtain some of the contained fluids for the purpose of making cultures. The swab is preferable to the platinum wire, because it does not cut the gelatine plate.

Dr. Hodenpyl said that he had used these swabs during the past winter, and had found them very convenient. They keep moist for some time.

Dr. F. Ferguson said that some years ago he had had Meyrowitz prepare for him a case holding twelve short test-tubes, containing agar-agar. These tubes were closed by a sterilized cotton plug, and a platinum needle extended from the plug to the agar-agar. It cost only five dollars. He could not see wherein Dr. Park's swab had any advantage over this.

Dr. Park replied that his case cost only eighteen cents; that he used cotton rather than a platinum point, because in the case of a struggling child it was much more difficult to use the platinum wire than the swab.

A Cheap Incubator.—Dr. Park also presented a model of an incubator, the cost of which would not exceed five dollars. It consists of a double boiler having a piece of lead attached to the bottom of the inner boiler so as to hold that vessel down during the ebullition of the water in the outer vessel. The boiler is surrounded by an asbestos jacket, and a piece of asbestos covers the lid. Through the centre of the lid passes a thermometer which serves to indicate the temperature within the boiler. The gas regulator consists of a bulb containing alcohol, and connected with a U-tube containing mercury. The boiler rests on an iron support, and a Bunsen burner furnishes the necessary heat.

General Tuberculosis.—Dr. F. Ferguson presented specimens from a case of general tuberculosis. The patient was a man twenty-eight years of age, who was admitted to the hospital on May 22, 1893. About two years before this, he said he spat up a large quantity of blood, and that during the past year he had frequently expectorated smaller quantities. He had had a cough ever since childhood, but recently it had become much worse, and he had emaciated rapidly. On the day before admission, he had a chill, followed by sweating, headache, pains across the chest, and prostration. There was slight dulness and high-pitched breathing over the left apex in front, and subcrepitant and coarse râles scattered over both sides of the chest, but most marked over the left apex and right base. Over the right base, posteriorly, there was dulness and slightly diminished voice and breathing. The free edge of the liver could be distinctly felt three inches below the free border of the ribs, and the spleen could be palpated two inches below the ribs. At the autopsy, there were found old peritoneal adhesions,

cheesy degenerations of the supra-renal capsule, pigmentation of the stomach, a cirrhotic liver with diaphragmatic adhesions, tubercular tracheitis, tuberculosis of the kidneys and prostate, and miliary tuberculosis and pneumonia in the lungs, one lung having a small cavity in the apex.

Supernumerary Pancreas.—Dr. George P. Biggs presented a specimen of a tumor found at the pylorus, in a patient who died of alcoholism. The tumor was exactly at the pyloric ring, and the mucous membrane covering it was thickened but intact. It was thought to be a fibroid, but a microscopical examination showed that it was a supernumerary pancreas. Dr. Biggs also showed several specimens of a partial separation of a portion of the pancreatic tissue, just over the head of the gland and projecting into the duodenum, and typical pancreatic tissue was found within the walls of the duodenum. He stated that this anomaly would be found in nearly one-third of all necropsies, if these were made with sufficient care.

Dr. S. T. Armstrong said he believed this was rather an instance of ectopy, properly inclusion, of glandular tissue, than of supernumerary gland.

Dr. Huddleston asked if there were also supernumerary ducts.

Dr. Biggs replied that ducts were found throughout the tissue, but no specially well-marked duct was found, nor could he say where these ducts emptied.

Old Appendicitis; Vertebral Abscess.—The President presented specimens taken from an almshouse patient, of whom no other history was obtained than that he could not walk, but could move his legs. There was an old appendicitis that showed a tumefaction of the appendix due to accumulated fecal matter. There was also a tumor over the fourth lumbar vertebra, from which, on incision, a quantity of pus escaped. The bodies of the vertebræ were found to have been eroded, and the accumulated fluid had compressed the cord.

The Society then went into executive session.

Correspondence.

ABDOMINAL HYSTERECTOMY WITH CLAMPS.

To the Editor of the Medical Record.

Sir: In a recent issue of the Medical Record dated July 1st, Dr. Emory Lanphear, of Kansas City, Mo., contributes an article entitled, "Abominal Hysterectomy with Clamps—A Rapid and Safe Method of Removing the Uterus," and dubs the operation Lanphear's without even as much as noticing my work on the same subject which was described a year ago and published in the Medical Record of November 19, 1892. As my publication contained all the essential features of the author's claims, and was the first supra-pubic clamp operation described, it would be in accordance with justice that my operation be recognized. Dr. Lanphear, although I had mailed him a reprint of my article, appropriates the honor of the clamp operation and sets himself up as its sole originator; of which claim the readers will be better able to judge by referring to the above numbers of the journal. No apology, on the ground of minor differences in the operation, is sufficient to excuse this injustice, inasmuch as the question at issue deals with the clamp operation. Total extirpation of the uterus by the supra-pubic route was decided upon and executed by me almost two years before my publication of the operation. At this time supra-pubic hysterectomy was not discussed, and the instruments and operation I described are in every way original.

Respectfully,

J. S. Pyle, M.D.

Canton, O., July 17, 1893.

The Livland Medical Society, of Russia, will meet in Dorpat on September 1st, 2d, and 3d of the present year.

A PRACTICAL VIEW OF BABY SHOWS.

To the Editor of the Medical Record.

Sir: Although the incident at the Melbourne Baby Show, reported in the Medical Record of July 15th, has its amusing side, does not the question arise among those deeply interested in the welfare of children, whether any action which might tend to raise the standard of development in early life, could be wholly undesirable?

Considering the wide-spread indifference regarding the proper physical development of children, and the prevailing ignorance as to the "points" a really healthy child ought to possess, it would seem that proud mothers might well learn a lesson from exhibitors of live stock.

One who, among intelligent people, has repeatedly seen the large head of rachitis pointed to with pride as an evidence of "brains," and heard the transparent delicacy of chronic starvation praised as "refinement of feature," cannot fail to hope for a day when the "standard of excellence" in babies shall be raised at least to an equality with that required for dogs and horses.

From this point of view, the Melbourne departure might indeed open "great possibilities"—not merely for the indigent doctor—as has been facetiously suggested—but also for the enlightenment of those entrusted with the care of the young and the consequent improvement of the coming generation.

E. B. Cross, M.D.

62 West One Hundred and First Street, New York.

AN INCIDENT IN SUMMER PRACTICE.—AUNT BETSEY HAWKINS.

By W. P. Northrup, M.D.,

New York.

"Aire yo-ou the doctor that cured Bill Jenkins's twin? Wa-al, I want ye to come along with me and see what's the matter with my mother-in-law; she's had some kind o' fit-like, and my wife thinks she has a touch o' paralysis." The person addressed was returning to the summer hotel, a little late for supper, the early intimations of evening already settling about the shrubbery and shady corners. The speaker was a back-countryman, shabby, thriftless, drunk. His greasy slouch-hat had settled into swells and cross-seas, the result of storms and spells of weather. From beneath appeared a sallow face, long straggling beard, and rat eyes. His shirt was open at the neck. His long-tailed, black coat hung in stringy folds from rather square, thin shoulders.

If there is one nuisance that worries the summer practitioner more than another it is the "native." To refuse to attend him is to appear inhumane; to treat him is to serve for trifling compensation and subject one's self to the most trying criticism. He is sure to come at five o'clock in the morning or at the dinner hour; and by the following noon all the county will know whether the city doctor's medicine is "any good." Furthermore, if the impression is favorable, it passes for a matter of course. This messenger wanted me to go at once in his shabby old wagon, somewhere out into the brush country, without supper, to be gone indefinitely. Refusal was out of the question; even slight delay was borne with frowning impatience.

"G'lang, Bill," said the codger, as he crawled in over the wheel, "he's better goin' toward home." During the first few miles of familiar road, the prematurely old man expressed his personal ideas of doctors. His wife had been the cause of his coming for me this time; as for him, he did not think doctors of much use. "No-ow do yo-ou, honest? Come, now, you're a doctor, answer me that." He continued: "When I'm sick I take a dose of Rochelle salts and in a day or two I'm as good as new." When it was "honestly" admitted to him, in the privacy of a rattling wagon, in the deepening shades of a lonely portion of the road, that he had the exact truth on his side, he let loose an explosive guffaw and lapsed into a moment's quiet.

All about was wrapped in evening. Long since the boys had stopped their games, the whip-poor-will his doleful call; the Bob-Whites were still, the sparrows and wrens had ceased their twitter, crickets and frogs had opened evening concert and were busy at it. It seemed, too, by chance we had happened in upon a family dispute among the katies. Without desire to intrude or place ourselves in embarrassing circumstances, we had unwittingly advanced into their very midst. There were sharp accusations followed by immediate flat denials. There was, perhaps, a trifling pause before the attack, but none before the contradiction. What the final outcome may have been we had no time to await, but as matters were going when we left, it seemed certain that the plucky pursuit of the katy-*did-n'ts* would eventually carry the day.

The disputant again showed signs of life and opened the discussion just where he left off. "I 'low we can't git along without doctors sometimes; you may need 'em to see folks, jest once, that's going to die, so's to give lines for certificate. You have to have the coroner if you don't, and the women ha ates that." In the daylight and in familiar country one may choose to defend his guild, but in a dark, lonely, country road discretion dictates caution. It subsequently appeared in conversation that my guide and drunken keeper had, in his palmy days, been a hanger-on at Harry Hill's down-town resort, was there, in fact, when the police descended upon it. Notwithstanding, I cautiously ventured to inquire what he would do in case of typhoid fever; would not a doctor have a certain function then? If I had rested my argument there, I should have been strong, but I unfortunately added pneumonia. That woke him up. "Fevers, ya-as; in fevers you can use a doctor, but good nursin's half the battle then, I b'lieve. Pneumony! (Scornfully.) No, sir! no doctor for me! Our Beaverhead doctor, he goes strong on my wife for nursin'; she's what I call a born nurse; she pulled me through pneumony, worst kind, twice—the doctor 'll tell ye so. Pneumony! Ask Dr. Cornstalks—yo-ou must a heerd of him!" I hastily admitted that I knew him well by reputation—had heard of his wonderful cures. For peace's sake, he should be, till we got out of the woods, President of the Beaverhead Academy of Medicine—anything, no matter how great. He began again later in somewhat more normal mood. "Bill Jenkins's twin they do say you fixed up very smart. S'pose you could a saved t'other? Bill's wife said she never give it the medicine that Queville doctor left; it was hot enough to burn the clinkers out of a coal stove; she tasted on it." No doubt my shabby friend had direct information from the Jenkinses, for Bill's business comprised, besides general groceries, all-around store and gin-mill as well.

The little old horse, headed for home, did very good work. The dashboard was high enough to nearly hide him, but every point of the argument was emphasized with a blow from the gad, which struck the dash first and bent till it found the animal's flanks. We knew the horse had been hit, for the backless seat let the passenger over nearly to the main-deck every lick and every jump. There were also frequent minor punctuations with spurts of tobacco-juice. After some miles the old horse abruptly changed his course several points. He left the main road and bolted into what appeared to be a field. As the old wagon skewed through the ditch and emerged with a tremor and a creak upon the dark background of grass or weeds, the following reassuring explanation reached me: "All right, Bill, yo-ou knowed the road." He further explained: "This is a highway, but it hain't been worked yet and it hain't been fenced." Certainly it was not straight, for we veered to the right and rounded a clump of bushes, then to the left diagonally, to avoid a cornfield, and headed for a light in the distance. The light was not our port, however, and after bolting down grade through an interval in what seemed, in the darkness, to be an overgrown hedge, the steering-gear doubled up sharply to the right and settled all fours into a heavy, sandy, single-track road. "No, not yit—got a long way to go yit," mouthed the tobacco-chewer. Slowly the poor brute toiled along this heavy road. Sometimes on even keel, sometimes with heavy lurches and much creaking, sometimes with a short scud, the craft with its deck passenger survived many perils. The high bushes on either side crowded upon the sand track into our faces, or frayed out upward against the gray sky. Occasional licks over the dash hunted out the animal; frequent spurts flew into the dark; mosquitoes—endless—discriminated in favor of the passenger. "See that there cross track," my drowsy friend hoarsely remarked. "See this 'ere old stump oak? That's the box-oak. That's the old mail route from Brooklyn to Sag Harbor. The driver tucked the mail for Queville into that holler tree and the folks come down and picked out their own things, or some o' the neighbors fetched 'em up."

Another silence. It was now night. The gray sky came down into the ragged tips of the wood; the bushes were solid black, the single track showing uneven stretches of faint gray. Betimes we passed among trees, then came upon dilatations of the avenues of bushes sufficient for vehicles to pass each other, and at length upon suggestions of a clearing. A moment later a huge dog bounded into the road and jumped at the horse's nose, good-naturedly barking and leaping in friendly welcome. "Hello, Tige, you knowed the old hoss, didn't ye?" drawled my reawakened driver, and, pointing with whip and arm, announced: "That light yunder's the place." He again subsided, this time apparently into reflections upon my backwardness in undertaking this journey without my supper or at all. "You-ou warn't in no hurry 'bout gettin' ready to come, I noticed; it's well fur yo-ou if she hain't no worse fur it."

The wagon hauled out of the two furrows it had fitted so well, creaked and wabbled over unseen mounds and obstacles, halting at last at the back-door of the patient's house. "Wa-al, Hank, where ye been so long; what become of ye?" came from a coatless, burly man standing on the one step before the door. A quart kerosene lamp, held high above his head, illuminated some five or six individuals wedged into the frame of the portal behind. "Got the doctor?" drawled the lamp-holder. "Ya-as," replied Hank (my fellow-voyager), "after findin' him and gittin' him." Having climbed down, in the blinding glare of the lamp, from the high platform wagon, and extricated myself from the friendly embraces of a great overgrown dog I stumbled into a wide kitchen, face to face with numerous women and men. Not quite sure of my reception, and with intent to clear up the mystery of my gruff companion and unknown company, I ventured, in my best form, the following feeler: "I hope your mother is better." The fat, double-chinned, two-story hulk before me proved to be the wife of Hank, wonder of nurses, general autocrat of the household. Addressing myself early to her highness and the fact that the patient was rather improving, allowed friendly relations to be quickly established. Then commenced, at once, a long story of the illness, everybody in the "swamp" being present and all standing in the middle of the low kitchen. The one lamp on a distant table made fantastic silhouettes of a most interesting group. Planted square before me, hands on hips, like a brick schooner wing-and-wing, was our prodigious spokesman in full illumination. Behind her, meek as Moses in the domain of his wife, was my disreputable friend Hank. The least interruption from him and he was snuffed out. Standing in the group were men in once red flannel shirts, rolled to the elbows, mouths open or closed on pipes, in all attitudes of uncouth awkwardness, but quiet as mice. The women, in men's hats or bareheaded, were fairly neat in person and looked intelligent and kindly.

At length, the informant and information exhausted, the shades and silhouettes commingled and resolved into a procession into the next room, up one step, around a corner, into a small lean-to—the sick-chamber. The kero-

sene lamp came to rest upon a stand at the bed's head, flooding the face of the sick one with a blinding light. The crowd of relatives and neighbors, in procession, halted at the door, some just inside, some within the frame, others on tiptoe peering past as best they might. The double-decked picnic barge, the born nurse, assuming her favorite attitude, began her story all over again, told it through, and once more recommenced. Her facts and fictions were neatly placed to strengthen her own theories, and when she was at length "held up," the attending physician was in gratuitous possession of diagnosis and prognosis, with frank suggestions as to treatment.

In the bed lay an old woman, toothless, sunken, wrinkled, gray. She was eighty years old, she said, and had never been sick in her life before. This time she must have eaten something that disagreed with her. What was it? Nothing different from usual. Cucumbers, green-corn, she admitted she had eaten that day, and succotash the evening before; but the aged patient declared she had eaten these things all her life, and they never hurt her the least bit in the world. It was thought best to take her temperature with the thermometer. "What's *that* thing?" she said. "No, I don't want none o' y'r new fangles; *I'm* all right." She shied and plunged like a colt. As to the pulse—the fingers were blue. Was her circulation so poor? The old woman parted her toothless, shrunken gums, and roguishly pointed to two large tin pails, which had originally held commercial white paint. "Huckleberries," she snapped out; "I was out a-berryin' this mornin' and there they be"—the entire audience laughing with her. From whatever indisposition the patient had suffered, she was apparently recovering, as she had done a hundred times before. It was subsequently learned that she had never been "quite so good in her digestion since she stopped smoking." For fifty years she had smoked her pipe after meals and taken comfort at her work. She was a good Methodist, and one day there came to their meeting a revivalist—a holy terror. In endeavoring to benefit the stolid multitude he had convinced her that tobacco smokers failed of attaining that happy state hereafter, for which she otherwise was fitted. She never smoked again. The patient was cautioned to be quiet and remain in bed till fully recovered, and we prepared to withdraw to another room. "Doctor," she called, "I must get out of this to-morrer, I've got a job of weavin' for Mrs. Newell." The speaker had for years done the weaving for Beaverhead County. She was an expert; could work in patterns, initials, figures, etc. In later years the demands were mostly for certain fuzzy rugs of soft gray, much admired by summer visitors to the South Shore. "In my day the girls was learnt to weave and spin," she cried, and spoke with bitterest scorn of "them pi-aner things."

Our aged patient was born on Long Island; had lived for thirty years in this house. It might be added that the pension and back pay of a worthless son had put several additions and lean-tos to this rambling building, and helped her hard earnings to support certain thriftless ones about her.

On the edge of the swamp was a small patch of ground which this hard toiler had spaded and sown to flax. Unaided she tended it, gathered, dried, bruised, hatchelled it, spun and wove the threads into fabrics, one of which I have held in my hands. Under the low roof of the garret was the loom at which the old woman had wrought through the long years. Where the bare rafters slope down to the low wall, she had labored till the excessive heat of the last summer made it impossible to remain longer. The bench and beam were worn and polished with long use, and had acquired a deep color from age. Behind the weaver's seat lay a pile of home-made shuttles polished and misshapen from wear. There were wracks, spools, swifts, reels, and many things which the daughters could neither explain nor name. As she toiled on through the long hours of the six work-days, the smoke of her short, black, clay pipe had curled along the slope to the peak of the roof, and died away among the odds and ends hanging from the rafters: dried inflated pig-bladders, bunches of dried herbs, rubber boots, powder-horns, etc. On Sunday the loom stood idle. It was a four mile walk through heavy sand to her meeting-house, but never since she "got religion" had she failed to be present, carrying usually one grandchild in her arms and helping another along by the hand.

After consultation apart from the patient, it was agreed that she might have suffered a slight stroke of paralysis, but that it had apparently "cleared up." She might live ten days, or she might live ten years. When she did pass away it would probably be from another stroke. A prescription was left with the hope of annulling any possible harmful effects from the cucumbers, corn, and succotash; light diet and rest in bed recommended. "Mother wants to see you again before you go," announced an attendant from the direction of the lean-to. On responding to the call the patient assured me, in a most cheerful voice, that she needed no medicine, that in a week it would be cool enough to begin work at the loom, and if I would come down she would show me what not another in these parts could show, viz.—weaving. Then after a moment's pause she asked: "What's y'r charges?" at the same time squeezing tightly a roll of bills. In a spirit of banter, "What you have there," was the reply. "No, ye don't," she promptly interjected, "ye shan't have it all; what's y'r charges?" The price was stated and paid. Raised on elbow she reached out a strong bony hand to say good-by—"and come again next week: I'll be weavin' then and I'll be glad to see ye. Ask at the edge of the swamp for Aunt Betsey's," and ducking her head smartly for good-by, she lay down on her pillow.

Out into the same high wagon with the low horse; from the glow to the darkness, over the same unevennesses, into the same sand-ruts, homeward. Good-bys had been cordial and good feeling prevailed. The box-oak was repassed, and we took a new way home, "Jest to show ye the bush," as my better-natured Hank explained. Farther on was a branching track to the right and a branch cleft in the black masses. "That road leads down to Bill Jenkins's," sheepishly remarked Hank, with a certain interrogative intimation in his voice. The old man's system seemed pervaded with an intense thirst; the old horse took it into his head we were bound that way and started to turn. Hank, receiving no encouragement and being reminded of the lateness of the hour, managed to head off the animal and guide him back into the long up-stretch. Behind were suddenly heard the footfalls of a flying horse, the whisk of bushes, and a hurried, wild, excited voice—"Hank, Hank, is that you?" A brief message was hurled at us through the darkness and the unseen rider was gone. The mother was taken suddenly worse, and would the doctor turn and come "quick." The clumsy vehicle, in some unknown manner, was doubled short about. The horse dove into the darkness, every jump marked by a swish of the gad in the hands of the charioteer. Horse and driver were transformed. We seemed to retraverse the distance at a pace hitherto inconceivable. I have no knowledge how it was accomplished; but bewildered, beswitched, blinded with sand, tumbled, and bumped, we drew near once more to the lonely habitation. Upon the road, some distance from the house, there emerged from the gloom a hatless man. In a voice husky and choking came the piteous cry: "Oh, Hank, it's too late! Did ye hurry y'r best?" Back over the sand-stretch he sped before us. This man I afterward recalled among the group, and located him as the one who listened intently but never spoke, and frequently slipped away in the direction of the sick-room.

As I dropped over the forewheel once more behind the rambling old house, quite a different scene awaited me. The interval had been short, but the curtain in the meantime had fallen upon that act in the tragedy and risen anew. Hank's wife was wiping the dripping tears from her big face, showing in her own way all the feeling of which her nature was capable. The numerous women

about the kitchen were stupefied, and stood with wide eyes and folded hands. The men, with heads bowed, silent, rested their faces against their hard, brown arms. Hastily passing through the rooms, I came to the lean-to where, white and rigid, in that attitude known as "laid out," was the hard-working, pious old weaver, the last of her kind. By her bedside, alternately kissing her motionless, upturned face, and drowning with hot tears an old wrinkled hand, kneeled the one son who had never been anything but a comfort to her.

Without warning, without a suspicion of its coming, a second stroke had quickly followed the first, and Aunt Betsey Hawkins was dead.

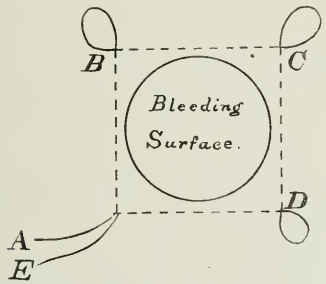
TONSILLAR HEMORRHAGE.

To the Editor of the Medical Record.

Sir: In your issue of July 1st I note an article by Dr. H. Hoyle Butts upon tonsillar hemorrhage, in which he discusses quite fully most of the plans of treatment heretofore suggested and finally pins his faith to a special clamp of his devising.

As it is evident that this gentleman is not aware of the simplest and most certain method possible—for obstinate cases—I would call his attention to the article upon this subject in your issue for December 17, 1892, to which he does not allude. This is the plan of ligation of the tonsillar stump by a buried suture. The appended diagram makes the idea plain at a glance. Since my original article (named) gives full details I shall not occupy your space therewith, simply adding that I have now at least a dozen times demonstrated at the Polyclinic that the method is easily practicable; that it can in case of need be done by sense of feel; that it does not take more than two minutes' time, and that it is absolutely certain in effect. I need hardly add that however ingenious Dr. Butts's device may be, it is certain that surgeons will purchase as few special instruments as possible; and that in this instance a long needle-holder, a semicircular needle, and coarse silk are alone necessary.

Perhaps I may modify my original paper by adding that I would suggest passing the needle the first time below, transversely (A to D in the accompanying diagram).



Often the bulk of the bleeding comes from ascending arteries, and in such a case one stitch placed here may suffice.

The following case exemplifies this:

On April 14th I operated upon Eunice S——, an anæmic child of twelve years of age, with very large tonsils and pharyngeal adenoids. The left tonsillar surface bled so annoyingly after amputation that having tried ice, and subsequently hot-water gargling to no effect, I passed a single transverse thread (A to D) one-fourth inch beneath the surface, intending to follow this with the other stitches. But upon drawing on this suture the bleeding was promptly checked thereby; and hence I tied it firmly and did nothing further. Thirty hours later it was cut and removed.

In conclusion I will quote a sentence or two from the letter of December 17th:

"The nearest approach to this idea which the writer has anywhere found is the method suggested by Dr. E. W. Clark, of New York, who has run two large needles through the bleeding base, and leaving these in place, wrapped a ligature firmly about them. Manifestly, even if this were equally as certain in effect it would be quite as difficult to do as the writer's device, and must be much more annoying to the patient while in position. Indeed, the side of the tongue would be likely to be lacerated against the sharp needles, unless in some way these were covered. The suggestion has also been made to seize with a volsella the bleeding surface, and drawing firmly upon it to tie a ligature about it. I have in one instance tried this, and found the ligature repeatedly slipping off, in spite of my best efforts. Indeed, as there is nothing like a real stump or pedicle left (if the tonsillotomy has been properly performed) such slipping is almost unavoidable.

"I only mention this latter plan as being the other of the two which remotely resemble the method upon which this paper has been written."

Very respectfully,

Robert H. M. Dawbarn.

New Instruments.

AN ANTISEPTIC NEEDLE-HOLDER

By John G. Jay, M.D.,

Professor of Principles and Practice of Surgery, Woman's Medical College, Baltimore, Md.

Although many forms of surgical needle-holders exist, there are comparatively few which may be strictly termed antiseptic, and some, in other respects good, are quite complicated in their construction.

As a holder composed of the fewest pieces, and having the simplest construction, is the most antiseptic, I have

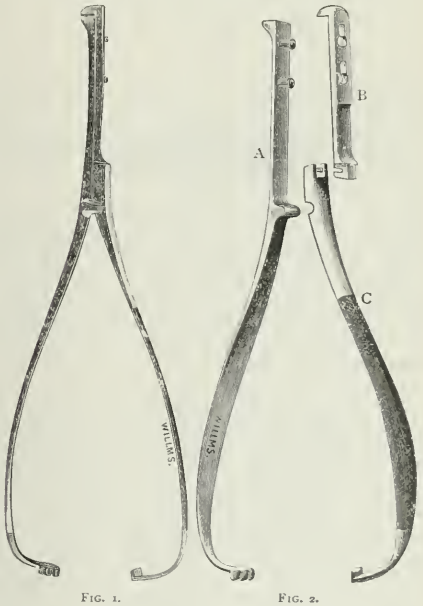

Fig. 1. Fig. 2.

endeavored to produce one of as few constituent parts as may be compatible with efficiency.

This holder, which I trust may be found useful to the

profession, consists of three pieces, and in most respects is, as far as I know, unique in design.

The accompanying cuts will, I think, quite clearly illustrate the plan of the instrument and its *modus operandi*: Fig. 1 shows the instrument complete, and Fig. 2 its several parts. The piece (A) Fig. 2, includes half of the handle and the blade or slide upon which (B) and (C) operate in closing the grip for the needle. Projecting from its surface of contact with (B) are two pins with heads, for the fenestra in the last-named piece; and toward the handle from these a fulcrum, with side guards, to fit the corresponding depression in (C). Piece (B) extends beyond the end of (A) with a sufficient space between the projections or jaws of the grip for the accommodation of the largest needle. At the other end of (B) there is a deep groove which fits upon a cross-piece or rivet in the end of (C). The portion of (B) between its attachment to (C) and the first fenestrum, is much thinner than the part beyond, and constitutes the spring. When the handles are compressed, the lever elevates the proximal end of the spring, draws (B) back upon (A), and very firmly closes the grip. At the same time the handles are locked. By unlocking the handles the spring, which was raised by the lever, resumes a position parallel to the other blade and the jaws are thus opened.

This may be called a universal holder, as it is adapted to the use of any variety or size of needle. It is simple in its construction, and I believe more easily operated and cleansed than any other of the holders now in use.

No claim of originality is made for the handle lock, it having been applied to a variety of instruments for a considerable time past.

The cuts are five-ninths of the size of the instrument.

I wish to express my thanks to Messrs. Willms & Co., of this city, by whom the instrument was made, for the care and skill which they exercised in its manufacture.

210 West Franklin Street.

A NEW KNIFE FOR CUTTING OFF DRY PLASTER-OF-PARIS DRESSINGS.

By A. M. PHELPS, M.D.,

NEW YORK.

The cut fully illustrates the form of the knife. It has a short hooked back made very strong. The handle is

massive steel ending in a wedge shape. This can be used as a lever from time to time as the plaster is being cut. Plaster bandages should be cut through their entire thickness with an ordinary knife while soft. This will aid the surgeon materially when the time for dressing occurs. Seize the edge of the dressing and cut, at the same time lifting so as to spring the bandage, and the knife will not bind. The handle used as a lever will assist the process.

40 West Thirty-fourth Street.

Formanilid: A New Analgesic in Laryngeal Diseases.—J. Preisach found (*Wien. med. Presse*, 1893, No. 10) that, after insufflation, pain in swallowing subsided in a few minutes, and that the effects continued from two to sixteen hours, usually ten to twelve. Palpitation of the heart and depression occurred in one instance, but lasted only a few seconds. With the anæsthesia of the mucous membrane its reflex irritability is likewise subdued. He finds it as active as cocaine, and much more enduring in its effects. A. Bökiai (*Ibid.*) recommends it in painful inflammations, as tonsillitis, pharyngitis, etc. M. Neumann first found biting and then numbness of the tongue from a twenty per cent. solution, with pallor and analgesia of the mucous membrane, the effects lasting an hour or an hour and a half.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 15, 1893.

	Cases.	Deaths.
Typhus fever	0	2
Typhoid fever	16	2
Scarlet fever	57	6
Cerebro-spinal meningitis	10	8
Measles	174	7
Diphtheria	107	36
Small-pox	9	0
Cholera	0	0
Varciella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

The Proportion of the Defective and Sickly among School-children has been shown in a striking way by a Committee of the London Charity Organization Society. After two years of labor they publish the results of an investigation into the physical condition of 50,000 school-children, all being children of the poor. It was found that of the 50,027 children, no fewer than 9,186, or 18.3 per cent., were defective in some way or other. Examining these 9,186 still further, we find that 5,851 showed defects of development; 5,487 presented abnormal nerve signs; 2,003 were delicate, pale, and thin; 3,679 were reported by the teachers as being dull in school; 1,473 showed eye defects; 67 were deaf; 239 were crippled, paralyzed, maimed, or deformed; 54 were epileptic; 234 were feeble minded; and 817 required special care and training. It is estimated that about 13 per 1,000 need special care and training.

Pills of Iodide of Potassium.—Here are some prize formulas submitted to the Pharmaceutical Society of Anvers as the best mode of making these pills:

℞ Iodide of potassium 0.25
Powdered starch 0.5
Simple syrup 1.0
For one pill.

Pulverize the iodide of potassium, add the starch in an impalpable powder, and add the syrup to make a pilular mass softer than an ordinary mass. One thing to observe is to work up the mass thoroughly, otherwise it does not present the desired cohesion. Roll the pill in starch powder. Another way is to take the prescribed quantity of iodide of potassium, dissolve it in a small quantity of water, add gum arabic in a sufficient proportion to obtain an ordinary mucilage, then add potters' clay in sufficient quantity to make a mass which can be easily worked, and immediately roll into pills, for in a short time the mass becomes hard. The pill can be rolled in potters' clay, or covered after the manner of iodide of iron pills. It is said that these pills keep perfectly without much care; they dissolve rapidly in water and after depositing the potters' clay give a liquid absolutely colorless.—*Medical and Surgical Reporter.*

Ante-mortem Will.—A story is reported from St. Louis of a man named O'Reilly dying of phthisis in a crowded hospital, who told a benevolent lady who visited the hospital with her daughter that he had made a will leaving the daughter $3,000. By the influence of this lady he was removed to a comfortable infirmary. Having found his little trick so successful, he tried it again upon the sisters, saying that he had amended his will, and left half his property to the institution. He was well cared for and properly buried, and it was not until some time after his death, when a dispute arose between the charitable lady and the infirmary, that it was discovered that he had absolutely nothing in the world.—*Medical Press.*

ELECTROLYSIS FOR THE RELIEF OF CERTAIN MORBID CONDITIONS OF THE NASAL SEPTUM.[1]

By JAMES EDWARD NEWCOMB, M.D.,

ATTENDING LARYNGOLOGIST DEMILT DISPENSARY, ASSISTANT IN ROOSEVELT OUT-PATIENT (THROAT) DEPARTMENT.

No application of electricity as a therapeutic agent offers a greater attraction than does electrolysis. Brought to a high degree of efficiency by Apostoli in gynecology, by Newman in urethral surgery and by others, it has enlisted the efforts of workers in every special department of medicine. Certain morbid conditions of the nasal septum have seemed to offer a field for a fair test of its usefulness. The present paper attempts to review the existing status of this special application of electrolysis and states the impressions derived from a very limited personal experience.

In 1800 Carlisle and Nicholson succeeded by this procedure in decomposing water into its constituent gases, oxygen and hydrogen. All binary compounds are resolved in a similar manner. When a ternary salt, such as cupric sulphate, is acted upon, oxygen and a free acid appear at the positive pole, while metallic copper is deposited at the negative.

When we pass from the category of inorganic to that of organic substances, we are confronted by a problem of much greater intricacy. We have, however, the same general class of bodies upon which to work. Living organisms of the animal kingdom are in this relation practically masses of cells bathed in a saline fluid. "An electrolytic disintegration of animal tissue consists in a resolution of the organized compounds of which it is composed, into their chemical constituents, acids, and bases."[2] "The results accomplished in the regions between the poles are owing to the influence upon nutrition: 1, of the chemical interchanges which occur throughout the circuit in the onward progress of the particles which eventually appear free at the poles; 2, to the circulatory changes resulting from vaso-motor action" (*ibid.*).

Let us study the matter a bit more closely. If we perform the simple experiment mentioned in all text-books on medical electricity, of inserting into a bit of beef muscle two needles connected respectively with the poles of a galvanic battery and pass a current of one hundred and fifty milliampères for two minutes, we shall hear a faint hissing sound, caused by the rapid production and escape of hydrogen bubbles from along the track of the negative needle. At the insertion of the positive, no such result is especially observed. The latter, however, becomes somewhat firmly imbedded in the muscle.

If we cut down on the track of the negative needle, it is found to be surrounded by a small cavity containing liquids and hydrogen bubbles. Along the original lines of contact between needle and tissue, the latter has been destroyed, for the walls of the cavity are soft, darkened, and a little pulpy. The needle is not eroded or tarnished. By a similar proceeding, the positive needle is found corroded and imbedded in a grayish eschar. The latter is stained in spots from a dissolving off of the needle. If the latter is made from a base metal, the liberation of its salts will stain the surrounding area; if made of gold or platinum, the tissue is unaffected by the nascent oxygen and acids. About the needle track we have the hardening and searing characteristic of an acid, while a very small cavity forms full of oxygen gas. Owing to the non-union of the latter with gold or platinum, these needles are not so firmly imbedded as those of base metals. The effects at the poles, therefore, in these and all similar experiments, are due to the nascent acids and alkalies. The destructive action varies also according to the nature of the tissue; the more succulent the latter, the greater the effect.

Rockwell remarks[1] that there is no evidence that organization, as such, seriously interferes with electro-chemical decomposition. The fluids of the body decompose under the influence of the current, just as the same combination of fluids with tissue would decompose if not endowed with life. The great difference in the effect of electrolysis on organic and on inorganic substances is seen after the current has ceased to act. The electrolysis of organic substances starts a process that continues long after the current has ceased to flow.

A rational view of the subject before us requires an answer to three main questions:

1. Is the tissue met with in spurs and deviations of the nasal septum of such a nature as to be capable of electrolysis?

2. Is the operation a safe and practicable one, and what is its proper technique?

3. Does this method of treatment possess any advantages over other methods, and what are the limits of its application?

First, then, as to the nature of the tissue with which we have to deal.

The nasal septum is made up of bone and cartilage covered with mucous membrane. It may be deviated locally or throughout its entire mass. There may be localized outgrowths from its surface. These two abnormalities may co-exist in varying measure. True cartilage is destitute of nerves, and therefore of sensibility. It is equally devoid of blood-vessels, except certain loops which run in here and there from the perichondrium. It is nourished by imbibition from the nutritive supply of neighboring parts. All cartilages, except the articular and fibro-cartilages, are covered with a fibrous membrane, the perichondrium, similar in structure and function to the periosteum. When cartilage is destroyed, it may be replaced by fibrous tissue or by bone, but it is never reproduced. Under the microscope it presents a colorless, transparent matrix studded with nucleated cells. These are flattened and arranged superficially parallel with the free surface of the cartilage, while, more deeply, they are elongated and grouped vertically. The nutrient materials absorbed by the blood-vessels are, by these cells, transmitted throughout the hyaline matrix. According to the need of tenacity or flexibility in cartilage, this hyaline substance is dense and more distinctly fibrillated.[2]

A true cartilaginous tumor is (Delafield and Prudden) usually hard, sometimes soft. The cells do not present the same uniformity in size, shape, number, and relative position. They may be large, spheroidal, and grouped in masses, or small and far apart. They are frequently fusiform or branching. Fibrillar connective tissue in varying quantity is usually present, either as a capsule or run-

ning in bands between the nodules of cartilage or passing as fascicles into them. The cartilage may change to mucous tissue, forming a myxo chondroma. The cells may undergo fatty degeneration, may calcify or ossify. Small hyperplastic growths on the surface of cartilage are called ecchondroses. The mucous membrane is the same in structure as elsewhere.

The abnormal physical conditions of the nasal septum are, for our present purpose, projections, thickenings, and local deviations. The two former are localized hyperplastic growths, *i.e.*, an overgrowth of normal tissue elements. The third variety is frequently due to an overgrowth of the septum as a whole, the latter being flexible as compared with the unyielding or rather the less rapidly growing bony framework in which it is set. The final causes of these abnormalities do not here concern us. Seiler states that, in those septal enlargements big enough to be regarded as ecchondroses, ossification has in most instances taken place.

From the foregoing statements, therefore, it will be seen that in those conditions characterized by an increase in varying proportion of the histological elements of the mucous membrane and subjacent cartilage, we have, despite the scanty amount of moisture, a fair field for success. I say a fair field, though perhaps not an ideal one. We have a cell collection permeated, along with its imbedding matrix, with a saline fluid, the liquor sanguinis.

Secondly: Is the operation a safe and practicable one, and what is its proper technique?

It is not a difficult task to collate the experience of others, as the literature of the subject is not extensive. As far as I know, all the work has hitherto been done by Continental and mainly by French rhinologists.

The monograph of Moure and Bergonie, to which extended reference is made farther on, is the present standard authority on this topic. It is interesting, however, to trace the gradual development of the method to its present grade of perfection.

In this special application of electricity, Miot[1] is by universal acknowledgment the pioneer. Others before him had already used it upon hypertrophied turbinated tissue, but he was the first to employ it upon the nasal septum. He employed a cylindrical speculum carrying a metallic collar, which in turn bore two slender supports for holding the conducting cords from the battery, thus enabling the needles, when once in position in the tissues, to so remain without being dragged upon by the weight of the cords. The speculum itself was of necessity made of some non-conducting material, such as varnished or shellacked wood, glass, or hard rubber. He employed both the monopolar and bipolar methods. In the former, one wire from the battery leads to the needle in the nostril, while the other is attached to a broad, flat electrode on some indifferent area on the body (arm, neck, etc.). Miot first made the indifferent electrode very small and of fuller's earth or of gelatine, placing it in the patient's nostril opposite the destroying needle in the other. He reported ten cases, all cured.

Garel[2] has given the results of some carefully conducted observations. He uses, first of all, an ordinary Duplay's speculum, only, however, for the examination of his patient and the insertion of the needles. He often omits the preliminary use of cocaine, claiming that there is only insignificant pain when the needles pierce the mucous membrane and no pain whatever when they finally rest in the area of selection.

This latter statement (it may be remarked), while anatomically correct, is clinically inadmissible. The average patient is far more affected by a pain produced in a part of the body away from his own observation than by the same amount of pain in a patent area. Inasmuch as we possess in cocaine an agent which in the majority of cases will prevent all pain, we should, it seems to me, always employ it unless there is some special contraindication. Its additional power to cause tissue anæmia is here only of secondary value, as one great claim for the operation is that it is practically bloodless.

Garel employs a slender pointed platinum needle, 3 to 4 ctm. long, inserted into a copper tube united with the negative wire. The needle is covered a varying distance with rubber, so as not to burn the skin, and is inserted 2 or 3 mm. deep in the region of the nasal projection. At first he used only a single point, but later has found it advisable to employ a small three-tined fork, the tips being near together. The cicatrix around this pole is soft and slightly retractile. The positive wire he led to a plate electrode covered with chamois or hydrophile gauze and placed upon the upper arm. On commencing treatment, his patients complained of dull pains in the nose. He could see bubbles of gas escaping at the site of operation, and on approaching the ear the faint crackling of the gaseous disengagement was audible. His *séances* lasted fifteen minutes, and a dosage of from 10 to 12 to 15 or 16 milliampères was registered On withdrawing the needle points, the sites of insertion were seen to be surrounded with whitish zones 4 to 5 mm. in diameter, and an eschar resulted, varying in size according to the depth of insertion. Two or three *séances* were often necessary to remove the offending mass. There were no disagreeable after-effects, except a little occasional headache. After some days the sphacelus was detached, leaving a sort of gutter-shaped cavity upon the salient point of the obstruction.

Garel has reported 30 cases thus treated, 26 men and 4 women, ages varying from five to sixty-two years. Eleven cases were between ten and twenty years; 12 between twenty and forty. Twenty-one cases presented a true, localized thickening from the normal plane of the cartilage, and in the remaining 9 the projection was associated with an adjacent depression. In 2 perforation of the septum resulted from the action of the current, but with no evil consequences. In 6 the operation was undertaken to obtain sufficient room for the subsequent removal of polyps. In one case, a nervous man, there was slight faintness at the commencement of the current; but he was quickly restored by the supine position, and was able to complete the *séance* without difficulty.

Peyrissac[1] reports a case treated by the monopolar method. His patient was a hospital interne, aged 26, who had nasal obstruction due to chronic coryza and enlarged turbinated bone on the left side. The right nostril was almost completely occluded by a septal spur, which impinged upon the inferior turbinated bone. The positive pole (a steel needle) was inserted into the spur and the negative (flat electrode) placed upon the nape of the neck. Intra-nasal insertion caused a momentary sharp pain in the incisor teeth. The current was quickly run up to 40 m.a., and the entire *séance* lasted twenty-five minutes. A ten per cent. cocaine solution was freely applied. The disagreeable subjective features were incisor pains, feeling of tension along the nose running to the cheek bones, a metallic taste at the base of the tongue, certain visual disorders, lachrymation, a sense of smoke in the room, etc. The needle was attacked for a length of 12 mm. Along the line of insertion was a grayish zone 4 mm. in diameter. The intensity of 40 m.a. was continued for four or five minutes, and held at 20 m.a. for fifteen minutes. A boric-acid wash was ordered. Slight pain in the nose continued for eight days, by which time the sphacelus had come away. A complete relief of all symptoms resulted.

Further contributions with reports of cases have been published by Botey,[2] Bolard,[3] Thilly,[4] and Strazza[5]. The first three merely duplicate the work of their French confrères. The article of the last named is not accessible to me. Bergonie[6] has made several observations in differ-

ent journals, but his views are fully embodied in the work next alluded to.

The foregoing *résumé* of the literature of this operation represents its status at the time when Moure and Bergonie[1] published their now classical monograph. They review the work of their predecessors, and express their hearty approval thereof. They have carried the technique to a degree of refinement not hitherto reached. They answer objections made by various rhinologists, and append a wealth of clinical experience. They discuss the general question under three headings:

1. Which of the two methods is preferable, the monopolar or bipolar?

2. In either case ought the electrolyzing points to be arranged singly or in series?

3. In the monopolar method which pole should be inserted in the offending mass, and where should the indifferent electrode be placed?

They answer these inquiries in brief as follows:

1. There are certain thickenings of the septum which have in proportion to their height a considerable prominence. Their base of implantation is narrow, and they can almost be regarded as pedunculated. Under these circumstances the monopolar method is preferable, but under all others the bipolar should invariably be selected.

2. A single point only should be used at each pole. Moure and Bergonie claim that since they have followed this course their patients have felt less pain, no perforations of the septum have occurred, and, except in very rare instances, the desired result has been attained in a single sitting. Somewhat elaborate diagrams are inserted in their text illustrating the "lines of flux" (Strömfaden) and the "lines of equi-potential"—that is, the direction and distribution of the current when acting upon tissue. Therefore, when only single points are used in either method, the lines of flux are concentrated upon the tissue to be removed, and not diffused over the surrounding normal area. We also avoid pain in the incisor teeth, salivation, phosphenes, metallic taste, etc., which all result from the lines of flux impinging upon sensitive nerve tendrils and ganglionic centres.

3. These observers find practically no difference between the destructive effects at the two poles. Garel prefers the negative pole.

The phenomena of reaction are less marked and the absorption of the necrosed mass more rapid.

Furthermore, G. Weiss,[2] in some interesting studies on the effect of electrolysis upon the essential elements of muscular tissue, finds no difference between the destructive results at the two poles. This latter observation is, it need hardly be remarked, distinctly contrary to the conventional teaching upon this subject. Moure and Bergonie find, however, that the detachment from the tissue of the positive pole very rarely causes a hemorrhage, while that of the negative is very often accompanied by a slight flow of blood.

Concerning the position of the indifferent electrode in the monopolar method, they express no positive opinion. Miot placed it in the patent nasal fossa; Peyrissac on the nape of the neck.

Since the work of Moure and Bergonie but one or two contributions to the literature of the subject have been made. Meyer[3] reported, before the Berlin Laryngological Society, December 2, 1892, a series of cases treated by the bipolar method. He used a sub-mucous injection of cocaine for the local anæsthesia. He carried, in some instances, the current up to a registry of 30 m.a. If there is any tendency to hemorrhage, he suggests a reversal in the direction of the current. Care should be taken to wait until the old eschar falls off before any renewal of the treatment is made. A neglect of this rule causes, Meyer believes, perforation of the septum, two instances of which occurred in his own cases. Otherwise he had no disagreeable results.

In the discussion which ensued on Meyer's paper, his optimistic views were confirmed by Rosenberg, but opposed by Flatau. The latter had tried the method, and abandoned it. He regarded it as painful, and had observed after it violent hemorrhages. Moreover, he believed that it destroyed only cartilaginous and not bony tissue.

Herying[1] reports three cases, all treated by the monopolar method. In two of them four sittings produced no favorable result. Owing to the pains in the head and teeth, the current could be borne for only two minutes (15 m.a.). To this short duration Herying attributes his lack of success. In one case a perforation of the septum resulted two weeks later in the shape of a long slit.

The bipolar method is doubtless the preferable one. The apparatus needed consists of: 1, a good galvanic battery of at least thirty elements and of a constant delivery; 2, a rheostat; 3, a reliable milliampère metre. It is advisable to arrange the circuit in the following order: Positive pole from battery, wire from latter to ampère metre, wire thence to rheostat, wire from latter to negative pole. The two terminal wires end in light clamps which support the needles. The latter are the ordinary steel sewing-needles of commerce. Those supplied for sail-makers are, from their size, finish, and fineness of point, in every way preferable. Their diameter varies from 0.5 mm. to 1.5 mm. and their length from 7 to 10 ctm. Steel needles are preferable to those of gold or of irido-platinum (Bergonie), because they penetrate the tissue more easily. No objection attaches to the possible action of the current upon the steel, because the salts formed thereby are salts of iron, not harmful and possibly hæmostatic. If curved needles are desired, the steel can be easily softened in the flame of a spirit-lamp and bent as desired. The attached ends are covered with a bit of fine rubber tubing (lengths of filiform catheters will answer), leaving exposed any desired length of point.

The depth of insertion varies, of course, according to the amount of tissue to be removed. The average duration of each *séance* should not exceed fifteen minutes, and the dosage should not exceed thirty milliampères; frequently fifteen are enough. In every instance the rheostat should be placed at the maximum of resistance, and then the latter be slowly and gradually diminished until the proper registry is observed on the ampère metre.

The object of all operations in the septal abnormalities is to detach the mass, in a section parallel to the normal plane of the septum, and the name proposed for this particular method is "electrolytic section."

It goes without saying that the rheostat and ampère metre must be carefully tested before the sitting is commenced. The current must be carefully raised to the maximum and as carefully lowered to the zero point. A boric-acid wash suffices to clear away the detritus about the needle-holes, and should be followed by an insufflation of some antiseptic powder (*e.g.*, stearate of zinc with aristol). An eschar is formed, which, after eight or ten days, comes away. As in all intra-nasal operations, it is impossible accurately to estimate the amount of space gained till several weeks have elapsed and the parts have had time to mould themselves into what will be their permanent shape. If the detachment of the sphacelus is only partial, some cutting instrument will easily pierce the small areas of adhesion. A galvano-cautery tip can be used to trim down any small excrescences which may remain about the edges of demarcation. No unpleasant after-effects are noted. In very nervous patients, or in those where a large area of tissue has been acted upon, there may be for three or four days after the sitting a slight pain at the root of the nose. Rarely the whole organ or one side of the face may be thus affected. The existence of pregnancy or the menstrual epoch contraindicates operation.

[1] Herying: Therap. Monatsschrift, January—February, 1893.

We now come to the last inquiry of our discussion Does this method of treatment offer any advantages over other methods, and what are the limits of its application?

1st. First in its favor is the fact that it is bloodless. The oozing which may result from the withdrawal of the needles never amounts to more than a drop or two, and may be disregarded.

2d. The field of operation can therefore be kept in view throughout the entire sitting.

3d. There is no after inflammatory reaction[1]

4th. There is practically no possibility of after-intranasal adhesions or deformity.

5th. It is claimed that it is painless, though Monre and Bergonie admit that in neurasthenics and occasionally in some others the use of cocaine does not entirely obtund the local pain.

6th. It is a possible alternative in certain cases of marked thickening, associated with deviation of the septum, where an operation for straightening the latter is deemed unlikely to prove successful. This latter procedure is confessedly one of the most unpromising, as to eventual results, in the whole domain of intra-nasal surgery. It is comparatively easy to keep the septum straight until the parts have healed; but months after it is frequently found that the deformity has returned, and occasionally "the last state of that man is worse than the first."

7th. Electrolysis will frequently be allowed by nervous patients who would refuse a cutting or boring operation of any kind.

8th. The laity attach such importance to the workings of electricity upon the human body, that this procedure might appeal to them when all others would not. This argument is, of course, puerile from a scientific point of view, but possesses, nevertheless, a certain ethical value.

In every country outside of France, rhinologists are wedded to the cutting and straightening forceps of various kinds, with subsequent technique, to the saw or to the trephine, drill, and burr. Certain of these measures require general anæsthesia. All of them are more or less bloody. After the first cut of the saw or thrust of the trephine the field of operation is obscured despite our utmost care, and we work by faith rather than by sight. Before it can be cleansed properly the effect of the cocaine wears away. Secondary or renewed cocainization often fails entirely with any safe quantity of this powerful drug.

So far as the pain is concerned, most operations with the drill and trephine are free therefrom; in fact, surprisingly so. The use of the saw is more disagreeable, as a longer time is required to complete the work. Thorough cleansing with subsequent antiseptic treatment and the sealing of the wound with collodion, as suggested by Freudenthal and others, render disagreeable reaction the exception and not the rule.

Somewhat against electrolysis is the fact that an elaborate outfit is required. Galvanic batteries are as yet the *bête noire* of physicians. Even the best of them are more or less capricious in their action. Furthermore, allowing that it takes the same time to arrange the electrical apparatus as the drill or trephine, the actual time of operation is much greater with the former than with the latter.

The histories of two personal cases, treated at the Roosevelt Hospital, Out-Patient Department (Service of Dr. Jonathan Wright), are herewith given. The apparatus used consisted of a thirty-cell Waite and Bartlett battery, horizontal ampère metre, carbon rheostat, and steel needles. The latter were No. 5, of the ordinary variety used by seamstresses, and measured about 5 ctm. long with a diameter of 1 mm. They were inserted in hard rubber handles, which were then bound together with silk thread, so that the needle points were about 1 ctm. apart. The bipolar method was employed in both instances.

Case I.—J. B——, male, German; aged sixty one; watchman. Father died of phthisis, aged seventy. Patient's previous health always good, except that he has been quite deaf for the past two years. No specific history, and no previous complaint of any nasal or throat trouble. For the past five weeks has noticed slight pain on swallowing; post-nasal dropping, with considerable increase of buccal secretion. Is short of breathing on lying down; no hoarseness or cough: digestion somewhat at fault.

Physical examination showed some post nasal catarrh, with a general hyperæmia of the pharynx and larynx affecting also the vocal cords. The uvula was somewhat enlarged. (A simple astringent gargle quickly relieved all throat symptoms.) The right inferior turbinated was also enlarged, and the cartilaginous septum was somewhat deviated to the left. About half way back on the left side was a large, blunt ridge, running downward and backward, touching the left inferior turbinated, itself hypertrophied; marked obstruction to air-current on left side; moderate pulmonary emphysema.

The septum was cocainized (ten per cent.) for eight minutes, and the needles inserted at about the middle of the ridge. Twenty cells registered 15 m.a., and the current was continued for six or seven minutes. Depth of insertion of the needles about 1 ctm. The patient complained of quite a little pain at the site of operation, and as this was a first venture it was deemed unadvisable to prolong the sitting. All disagreeable sensations ceased on withdrawing the needles, and there was no bleeding. Antiseptic wash was ordered for the nose.

Four days later the patient was seen again, and it was estimated that the offending mass had lost about one-third of its bulk. The treatment was repeated as above. At the third visit it was noted that the mass had still further decreased in size; but a small, round perforation was noticed at the site of the first insertion. The patient then passed from under observation, and the ultimate condition is not known.

Case II.— B. W——, female, German; aged twenty-two; married; housewife. Family history good. Previous personal history negative. Married seven years; no children, or miscarriages. Has had occasional slight cough for the past seven years, rather more the past three months, during which time she has had nasal stoppage on the left side with frontal headache and a sensation as of a foreign body in the back part of the left nostril.

Physical examination showed the cartilaginous septum deviated to the left posteriorly with a blunt spur on its left anterior inferior aspect projecting nearly one-half inch from the septal plane. Electrolysis applied as in Case I. (cocainized), 9 E. = 9 m.a.; duration five minutes; very slight pain in nose. Two days later spur seemed reduced nearly one half. Electrolysis was again applied; but 2–3 m.a. for five minutes caused considerable intra nasal pain; and if current was increased this was felt also in the incisor teeth. Patient complained of some pain after the needles were withdrawn. Five days later, October 19, 1891, third sitting, 20 E. = 10 m.a., five minutes. No disagreeable sensations. Spur still further reduced in size.

October 21st.—Cautery to left inferior turbinated.

October 23d.—Cocaine fifteen minutes. Contact of needles seemed to cause intense pain, and patient became somewhat hysterical, requiring a discontinuance of the sitting. Potass. brom., gr. xv., given four times daily.

October 27th.—Tried 20 E. with same result as at last sitting. Pain even more severe. This disagreeable experience was again felt on November 3d, so that the last two sittings had no effect on the eventual result. Patient again seen December 7th, when it was found that the spur had entirely disappeared. There was some post-nasal dryness, but all intra-nasal symptoms had disappeared.

[1] [Schönemann reported, before the Berlin Laryngological Society, Session of April 24, 1893, two cases of electrolysis treatment, in one of which caries of the septum had followed operation. In the ensuing discussion Peltesohn and Rosenberg denied that the condition described was one of true caries.—Revue Mensuelle de Laryngologie, No. 10, 1893.]

The data furnished by these two cases are, of course, entirely too meagre to afford a basis for any comprehensive opinion, but one has impressions from every case, and these two cases demonstrated to the writer's satisfaction the feasibility of this plan of treatment. At the same time he believes that the use of the trephine would have brought about the same results far more quickly, and that is, after all, his belief thus far in regard to the whole matter, viz., that whatever can be done by electrolysis can be, by other means, accomplished more quickly. On the other hand, after making all due allowance for Gallic optimism, the statements of the Continental workers cannot lightly be thrust aside. Electrolysis ought not, therefore, to be at once placed under the ban. It deserves a further trial, which the writer hopes to make. With additional experience and improved technique, his future reports may assume a more hopeful and enthusiastic tone.

118 West Sixty-ninth Street, New York City.

SOME FACTS REGARDING CHINESE MEDICAL PRACTICE, WITH A BRIEF HISTORY OF THEIR METHOD.

By JAMES J. GREGORY, M.D.,

FOO CHOW, CHINA.

PRINTENDENT WILSY GENERAL HOSPITAL, &c.

The Chinese have received the credit of possessing a written language second only to the Hebrew in the date of its origin; and although they have had at all times numerous and prolific writers, still the history of the Chinese is strangely unreliable, being a sad mixture of sense and nonsense, fact and fancy. So thorough is this admixture and so determined has been the seclusion of this nation, that much of its history prior to the remarkable visit of Marco Polo in the thirteenth century A.D. must forever remain enshrouded in doubt. It is therefore a most difficult task, and at times an impossible one, to eliminate the errors that have been gathering for ages in the records of China, and place before the reader only unalloyed truth. Owing to this condition of things, it is little wonder that enthusiastic writers give some surprising accounts from time to time regarding the wonderful achievements of the ancient Chinese in the paths of science; but I think that in every instance of this kind we are justified in entertaining doubts as to the accuracy of such statements, for these writers are invariably prejudiced in favor of the Celestial Kingdom, and can find in the historical records of the Chinese a basis for illimitable flights of fancy: reasoning from analogy, they record as true many very questionable parts of Chinese history. The Chinese are now and always have been a poetic, superstitious race, notwithstanding their stoicism; and being in a lofty state of paganism it is perfectly natural that they should worship numerous deities. Some of these are reverenced for their reputed feats in the art of surgery, or for the miraculous cures they have wrought; but many of these gods are as purely mythical as are Esculapius and Hygeia of the Greeks, while the remainder if shorn of their antiquity would speedily fall into disrepute.

An abundance of evidence can be adduced to show that Chinese knowledge of all matters of education is as perfect now as it ever has been, and that their ability to arrive at ultimate principles is fully as great as it was two thousand years before Christ or at any other period of their existence; and we find China to-day absolutely barren of science.

If scientific medicine and surgery had ever been known to the Chinese, as some would wish us to believe, some traces of them at least would have been preserved in their historical records; whereas we find running through all their literature of this subject, from the earliest times down to the present, accounts of the anatomical construction of the human body and of its physiology so glaringly inconsistent with the facts as we know them, that we are forced to deny them the renown of ever having possessed a knowledge of a subject the very foundation of which they have shown themselves so densely ignorant.

The statement has been made by someone that "the Chinese must have dissected in earlier times to have possessed so good a knowledge of minute human anatomy," but a mere glance at some of their anatomical and physiological teachings, and which they implicitly believe, will readily show that they know next to nothing of even the grosser parts of these subjects. All the great authorities, living or dead, teach that the lungs are divided into four large and two small lobes; that the larynx passes directly into the heart, and that the small intestines are intimately connected with the latter; the liver has seven distinct divisions, and the skull, the framework of the fore-arm, pelvis, and leg consist of a single bone each! The heart is the organ of thought. I may say, parenthetically, that I have not been able to find a Chinaman who thinks that he is the fortunate possessor of two hearts, as some writers have observed. Schemes emanate from the liver, and courage resides in the gall-bladder. Hence the bile of tigers and lions is taken by those who wish to enter the lists for bravery. The urine passes at once from the small intestines into the bladder through the ileo cæcal valve. The kidneys of males secrete the seminal fluid in conjunction with the testes, which are called the "outside kidneys," while those of females have some mysterious influence over the function of menstruation. They entertain vague and numerous ideas regarding generation. By the quality of the radial pulsations of the right hand in man, and the left in woman, they pretend to be able to understand the condition of the lungs, spleen, intestines, and right kidney; and that by palpating the pulsations of the opposite hand, the condition of the heart, liver, and left kidney is revealed to them. It will be seen that they are in blissful ignorance of the true function of circulation.

The cerebro spinal and muscular systems and osteology are almost entirely ignored by them as being of but little real importance in the human economy, and the absorbents seem to be quite unknown. Therefore the pulse, which is the index to all organs of recognized importance, always receives the lion's share of attention. Judging strictly by our present light and without drawing upon our imagination, we can be very sure of the actual status of the practice of medicine and surgery of the Chinese in the past and at the present time; and we will receive no inconsiderable aid to an opinion concerning its future if we examine the teachings of the two great religious or moral leaders of this people—Buddha and Confucius—whose following for centuries has numbered, with unimportant exceptions, the entire population of China. It is the *summa summarum* of ancestral worship to "serve the dead as the living, the departed as the present." Thus Confucius, five hundred years before the beginning of the present era, established a most formidable barrier to the extension of scientific medicine in China by preventing the study of anatomy on the cadaver and all research in the field of pathology; and this obstacle is liable to retain its formidability for generations to come. It is true that a few post-mortem examinations have been secretly held in the name of science by foreign practitioners on the bodies of natives, but it is a courageous and not altogether thoughtful person who would undertake to do this under the present *régime*. Buddha, whose memory our friends the clergy and laity of Great Britain are now striving to keep green, was the king of anti-vivisectionists; and due to the zeal of his followers the study of practical physiology and therapeutics is more sadly handicapped here than, let us hope, it ever will be in countries enjoying a higher state of civilization. These questions and others quite apparent severely militate against the possibility of any appreciable change in medical practice here in the near future; time will have to be given in order to educate the masses of the people up to the Western standard before Western medicine can

be taught with safety, or even practised in its fullest, highest state of perfection upon Chinese territory.

There is good evidence to establish the claim that the Chinese were the first among nations to found anything approaching a system or method of practice, and the native medical fraternity takes the greatest possible pride in this its single distinction. I should not like to be understood as saying that theirs is a systematic scheme by any means, but as there is no other term to express my meaning briefly, I shall use it and other terms throughout this article metaphorically.

Their medical literature demands our consideration, if not for any valuable additions to science contained therein, at least for the vast number of its authors and for the historical interest attaching to a method which has extended over so many centuries. In the reprehensible command of the Emperor Che Hwang Te (214 B.C.) to burn all books in order that Chinese history might begin with his reign, exception was made of all books bearing upon the subject of medicine, and we thus have an unbroken and very long line of literature.

Probably the oldest "medical book" extant is one containing all traditional knowledge of medicine handed down from the most remote times, and is said to be from the hand of Hwang Ti (2697 B.C.). Be this as it may, there is good reason to believe that it antedates all works of a similar character, whether by Hippocrates or other ancient writer. The same author has written a voluminous work on "Internal Maladies" and acupuncture, which, after being revised in the eleventh century A.D. by Wang Ping, now forms the standard authority on these subjects. From the time of Hwang Ti to the present, there has been a constant production of books on the practice of medicine, some of which are marvels of patient industry and perseverance, as a few citations will corroborate. Nearly every doctor in the past three or four thousand years who has had a grain of ambition in his make-up has published his "Notes on the Pulse," "A Guide to the Pulse," or something else regarding this fetich of the Chinese, and there is consequently an extensive and most fanciful literature of this particular subject, which is after all so little understood by them.

Choo Suh, an Imperial prince of the early Ming dynasty, wrote a "Guide to Therapeutics" of one hundred and sixty-eight books. The author writes nineteen hundred and sixty essays on over two thousand different subjects, compiles more than twenty thousand prescriptions, and uses two hundred and thirty-nine diagrams to aid the text.

The great materia medica of the Chinese was finished in the sixteenth century A.D., and is complete in fifty-two books. Le Se Chin, the author, made extracts from upward of eight hundred authors, and consumed thirty years in the preparation of this work. It contains eighteen hundred and ninety-two remedies arranged in sixty-two classes under sixteen general divisions. The text is supplemented by numerous illustrations, and under the name of each substance there are copious explanations, to which are appended the physical properties of the drug and its applications, with prescriptions. This effort in book-making is a credit to the country as well as to the author, and is an excellent example of the incomparable tenacity inherent in the Chinese.

The Chinese materia medica offers some possibility of reward to diligent investigation. Some work has already been done in this field, but there remains a vast unexplored region which may hold many gems of priceless value to the human race if they could only be brought to the hand of the skilled pharmaceutical lapidary.

Much of the active principles of Chinese drugs must remain hidden to them, and enter and leave the body with negative physiological manifestations, because of the crude and primitive methods employed in their preparation and administration; but even under these disadvantages, no one who will take the pains to observe can deny to the musty prescriptions of Le Se Chin a certain potency. While the materia medica contains much of value, it also has classified as remedies substances which are too loathsome to admit of mention in English print, and must be submitted to ocular demonstration to convince the nineteenth century European of their existence. These indigenous products we abandon at once with no thought of investigating their claims to virtue, believing that *ægrescit medendo*, let the disease be what it may.

Then again there are substances occupying an intermediate position between the undoubted good and the worse than worthless, which by their oddity attract our attention and compel the question whether there may not possibly be some subtle virtue in them after all. This possibility receives strength from the fact that these people, who have an international reputation for their love of money, place such confidence in the healing powers of this class of remedies as to pay fabulous prices for them.

There are no institutions in the Chinese Empire devoted to teaching native medicine. There is a medical body at Peking, which has been called by some writers the "Imperial Medical College;" but this translation is in error, and it would be more nearly correct to speak of this organization as the Imperial Medical Board; for it neither teaches medicine nor grants certificates to practice, but its principal function is the care of the Imperial Family. This Board has some nominal authority in medical matters throughout the Empire.

The meagre education possessed by Chinese doctors is generally acquired, first, by reading; and lastly, from the clinical instruction of a preceptor. The reading covers any length of time, depending entirely upon the ambition of the reader; for there are no legal requirements to be met in this, and only absolutely inactive laws governing his deeds or misdeeds as a practitioner. His study is supposed to include the nine branches recognized by the Imperial Board, and are as follows: Diseases of the great blood-vessels and small-pox; diseases of the lesser blood-vessels; fevers; female complaints; cutaneous diseases; acupuncture; diseases of the throat, mouth, and teeth; and diseases of the bones.

When the medical student is apprenticed to some established doctor, he is admonished to persevere in his efforts to "understand" the pulse, for as no man has yet succeeded in fathoming these immeasurable depths, it stands him in hand to be diligent in this if he wishes to gain distinction among his fellows.

Besides the attention given to the pulse, the student while with his preceptor must learn to compound prescriptions and the art of acupuncture and the other very simple surgical operations performed by the Chinese.

The time to be spent in this way, like that at his books, is purely optional with the student; and he is permitted to "hang out his shingle" just when it pleases him to do so.

As already noted, there are no active laws controlling practice in China; however, Sec. ccxcvii. of the Code orders that "whenever an unskilled practitioner, in administering medicine or using the puncturing needle, proceeds contrary to established forms, and thereby causes the death of a patient, the magistrate shall call in other practitioners to examine the medicine or the wound, and if it appear that the injury done was unintentional, the practitioner shall then be treated according to the statute for accidental homicides, and shall not be any longer allowed to practice. But if designedly he depart from the established forms and deceives in his attempts to cure the malady in order to obtain fees, then . . . he shall be treated as a thief; and if death result from his malpractice . . . he shall be decapitated." This is stringent legislation indeed, and if it were to be enforced would soon result in a dearth of Chinese doctors: it is in fact simply a dead letter. The district magistrate or his deputy alone holds inquests on all cases of accidental death, suicide, and homicide; and money almost invariably secures pardon to the homicide, whether he be doctor or layman, even though an innocent vagabond or a petit criminal has to be sacrificed for the sake of appearances.

A doctor may set up as a general practitioner or elect to practice as a specialist, just as he desires. So we find the "all 'round doctor" the specialist in each of the nine branches, and numerous others practising as specialists in departments not included in the official schedule.

The obstetrical field is entirely in the possession of the midwife, except when foreign physicians are available. It is true, a woman in the beginning of labor generally receives a visit from her doctor, who sends medicine which is intended to allay the pangs of childbirth; but the entire conduct of the labor is in the hands of the midwife, who makes all necessary examinations, directs the attitude of the parturient, and on the whole is a martinet in the lying-in room. In all cases of normal labor the patient does not assume the decubitus, but kneels on the floor with a small wooden tub between her knees to receive the discharges, or sits on two chairs which are widely enough separated to admit delivery between them. When the child is born the midwife ties the cord, and cuts it with some dull article, such as a knife made of bamboo or a piece of broken crockery. Unless the afterbirth now presents, the patient retires to her bed, and the third stage of labor is completed in the recumbent posture. The parturient is left quite undisturbed. There are no vaginal irrigations, no binders, and no means, internal or external, employed to insure the involution of the uterus. The omission of support to the relaxed abdominal muscles, and through them to the now empty uterus, is undoubtedly much less felt by these women, whose muscles and viscera have not become habituated to the use of stays, than it would be by their Western sisters. If the labor be protracted the midwife endeavors to determine the cause, and if due to malpresentation strives to overcome it; and some of these attendants attain to considerable skill in this, when we take into consideration the erroneous ideas they possess of the mechanism of labor and of the anatomy of the parts involved. When the labor is very prolonged, often lasting several days, the patient takes her bed from sheer fatigue and resigns her body with superhuman fortitude to the horrible mangling of the midwife. When an extremity presents and delivery cannot be effected by traction applied to this, the attendant hasn't the slightest hesitation in removing the offending member with a kitchen knife. It is due her, however, to say that this is seldom or never resorted to until viability is supposed to have ceased. The only "instruments" used by the midwife are the knife referred to and a small sharp iron hook. Natural labor is apparently very easy with the Chinese woman, and it is not unusual to find her up and dressed within a few hours after delivery, although a woman of the higher classes is expected to keep her room for about one month.

There is no scale of charges for attendance on the sick, a great deal depending upon the character of the illness and the social and financial standing of the patient. The theory is "no cure no pay," except chair or cart hire, which is always paid by the patient. If a doctor is called to see a case which in his opinion cannot recover, he never leaves or prescribes any medicine, but simply takes his quiet leave, with no thought of rendering a bill for the visit; and the friends of the sick prepare to go into mourning or seek another doctor, just according to the degree of confidence they have in the one who has made his gloomy prognosis. When a patient is first seen by a doctor the following routine is strictly adhered to: The doctor searches the face, asks to see the tongue, listens attentively and with Job-like patience to all the patient and his friends have to say concerning the past and present illnesses with which the patient has been or is afflicted, and then, after a sufficiently long pause to lend dignity and *éclat* to the announcement, he gravely states his desire to examine the pulse; it is at this stage of the proceedings that a scene is generally enacted which sorely tries a Westerner's gravity. One would think that, as this announcement had been made at every attempt at diagnosis for pretty nearly four thousand years, it would by now have become a trifle commonplace. But not a bit of it. The pulse (I always feel like using the capital when writing it of late years) is too mysterious and hallowed a thing to be degraded by the simple flight of a few tens of centuries; and as the doctor begins his palpations by placing three fingers first upon one radial and then upon the other, for reasons given elsewhere, the sickroom, which is generally filled with the relatives and neighbors of the sick and has up to the present been a second Babel for noise, is suddenly hushed and word is passed, "The pulse is being examined!" and upon the faces of many is plainly written reverential awe.

The patient, when the doctor is ready to examine the pulse, clears his throat, often performing a series of expectorations, and then calling for a book, a cushion, or a low stool, upon which to rest the arms if lying down, composes his body and submits to the ordeal. It matters not whether the disease be local or general or both, the pulse is invariably attended to, whereas the local conditions are frequently entirely ignored. They would as soon think of holding an autopsia cadaverica as of inspecting, ocularly, disease located about the genital and anal regions.

The Chinese doctor believes in and practises polypharmacy to a superlative degree, and he has learned that results can only be obtained from his crude preparations by the administration of surprisingly bulky doses. A single dose of medicine is prescribed, and if relief is afforded the patient it is repeated and continued until the patient is well, or until it fails to fulfil the expectations of the sick or his friends. If the patient at any time does not experience the benefit he thinks he ought from taking a medicine, his doctor at once tries something else, with no thought of questioning the wisdom of such an act. The doctors have a very convenient habit of screening their ignorance, if a disease pursues the even tenor of its way despite their efforts to retard it, by saying that it is caused by the presence within the patient of one of the many evil spirits which are recognized in China. Medicines having no influence over this class of cases, religious incantations are resorted to with a view of dislodging the enemy. These performances are varied and interesting to the student of psychology; but their details do not concern us now, and I shall only remark that few actual invalids survive the fearful din. The credulous continue to be duped, however, by promises of reward in the future life, if life here cannot be prolonged.

Their "external treatment" of disease, as they term surgical practice, is quite as empirical as their practice of medicine. The results of surgical treatment, generally appealing directly to the mind through the sense of sight, which is less liable to err through psychical influences than are the other senses, force the Chinese to accord to foreign surgery a superiority over their own manipulations, which defence Western medicine is somewhat slower in securing. Their surgery is based upon the theory that there are intimate connections between the external surface of the body and the structures within, and that treatment applied externally not only affects the immediate tissues, but their deep connections as well. Charts of the body surface have been made, mapping out three hundred and sixty-seven distinct areas, with their minute inner connections elaborately detailed. With this theory dominating practice we cannot be surprised at the frightful results of treatment and neglect to be found on every hand, and in such abundance as to place China in the unenviable position of being the richest country in surgical cases on the face of the earth.

Owing to the almost entire absence of complicated machinery in mine, factory, and transit, there are comparatively few of the severer accidents characteristic of the densely populated regions of the Occident; and when these do occur little help indeed is afforded by the native surgeon. Capital operations are never done, dislocations seldom reduced, and fractures only ineffectually supported —and generally the member is splinted up in the position assumed at the time of the doctor's visit; the results can

be readily imagined. They have no mechanical skill to enable them to ligate a bleeding vessel, even though it is freely exposed, and no anatomical knowledge to direct them in making appropriate compression. Because of this they are thrown into a panic at the appearance of even a slight bleeding, and exert themselves to the utmost to avoid inducing hemorrhage; and their every surgical interference—with a single exception to be noted hereafter, which is done, however, in compliance with the commands of the Emperor, who assumes all responsibility—is carefully planned to this end. When bleeding occurs, the application of some styptic—such as cold water, strong infusions of tobacco, tobacco leaf cut fine, powdered ginger, ashes, etc.—to the part is the only means they employ to stanch the flow.

Incised wounds are occasionally stitched, but as the Chinese are entire strangers to antisepsis, or common cleanliness even, the object of the suture is rarely attained. In general, however, small wounds and discharging surfaces are sealed with a black plaster, which is worn until it drops off; while over the larger sores is bound an oiled paper, which most effectually retains the acrid secretions, rapidly making a bad matter worse.

A slight hare-lip is sometimes made to unite by inducing granulations by the application of an escharotic; lateral pressure being employed during the granulating period. Attempts are made to relieve the very common entropion by planting an eschar on the redundant palpebral fold, either by a caustic application or by clamping a portion of the skin between two pieces of bamboo, which are left to slough off. Tumors of whatever character, and when offering sufficient promise of cure for a doctor to risk his reputation upon the trial, are sometimes treated by the application of strong caustic in the form of a plaster; this, with the omnipresent dirt, induces general sloughing of the tumor, which, if benign, and the patient rugged, may be finally eliminated, but with a most unsightly eschar on its site.

Acupuncture receives the same proportion of attention from the Chinese surgeon that the pulse does from the physician. It is practised in every possible variety of accident and disease, from a dislocation to a gleet.

The needles used for this purpose are of steel or silver, and are made in nine different forms, from the short thick arrow-headed form down to the long slender needle proper. When it has been determined to perform acupuncture in a disease or injury, one or more of the three hundred and sixty-seven areas supposed to be involved is selected, and a needle of the proper form, either heated to a dull red or quite cold as the case appears to demand, is slowly pushed into this area, often to the depth of several inches or until the needle impinging on bone renders its further introduction impossible. This is as barbarous as it is foolish, but it is something remarkable to note the amount of this indiscriminate prodding the human body will tolerate.

Counter-irritation is another very popular mode of treatment, and it has a wide application. When energetic irritation is indicated the moxa is invariably used; this is extensively used in the algid stage of cholera, and often with undoubted benefit. There are many ways of producing a milder form of counter-irritation, but the one in greatest favor, and which is practised much by the laity, is by nipping up a portion of skin between the knuckles of the index and middle fingers or between two coins: this process is continued until a deep ecchymosis is produced which lasts for several weeks. It is a common and grotesque thing to see these purple spots upon the temples, between the eyes, over the gullet, or upon the extremities of the people who daily throng the streets.

The only operations performed which involve the use of cutting instruments are the occasional lancing of a very superficial abscess by an unusually bold surgeon, and castration. Archeotomy is sometimes performed as a mode of punishment for certain grave crimes, and is always done to provide servants for the Imperial Family. A Chinese razor is used for opening abscesses and a sickle-shaped knife for the castration. There is a place, near one of the gates of Peking, where the royal servants are "prepared." At one sweep of the knife the penis and scrotum with its contents are removed on a level with the skin of the pubes, a metal plug quickly inserted in the urethral orifice, a cloth wrung out of cold water firmly bound on, and the "operation" is completed. At the end of three days, during which time the patient has been forced to abstain from drink, the initial dressing is removed and the bladder allowed to evacuate its contents.

This proceeding seems to be fairly satisfactory in its results, as only about two per cent. of the cases prove fatal from all causes. This mutilation is frequently self-inflicted by the Chinese as a penance for transgression of the seventh commandment; of these self-inflicted cases a large per cent. recover.

They are quite ignorant of anæsthesia; however they use opium, cannabis indica, and datura stramonium to produce narcosis, which may be so profound as to render painless many of their surgical procedures, but this cannot by any possible stretch of the imagination be classed as analogous to the valuable discovery of Guthrie and Liebig.

The medical fraternity possesses the characteristic conservatism of the race, and we find very few measures in general use which are not of undoubted Chinese parentage. In fact, I can now only recall three agencies that have been introduced into China from other countries, and which are used by the native doctors in the prevention and treatment of disease. These are vaccination, opium, and cinchona. Vaccination against small-pox was introduced to the notice of the Chinese in the eighteenth century, probably soon after its discovery; and they have not been slow to recognize in it a powerful defence against a blighting enemy.

WHAT THE POOR MAN CAN DO TO ESCAPE CHOLERA—AND THE DOCTOR.[1]

By EDWARD M. SCHAEFFER, M.D.,

BALTIMORE, MD.

MEMBER OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF PHYSICAL EDUCATION.

Be not dismayed though germs pestiferous infect the sky
And scientists delight to rouse them from their lair;
For healthy tissues germicidal are,
And normal functions duly exercised will scare
From uncongenial soil these low bacteria.

SINCE devoting my medical thought and endeavor to the prevention rather than to the cure of disease, and toward arousing in the public mind an enthusiasm for healthy living and physical perfecting, it is with even a sense of satisfaction that I admit that my knowledge of cholera is entirely second hand and my acquaintance with disease rapidly narrowing in favor of a specialty of health.

The Sabbath was made for man, and modern man, it might be inferred, was designed for the amusement and support of germs; ergo, why are not germs entitled to their day of rest, lest in the rounds of so general a practitioner they too succumb to nervous prostration and overwork? "To the germ theory, now accepted by a large majority of the profession, we are indebted for the recognition of the true agencies operating in the spread of cholera, and consequently for an ability to better meet them and neutralize them." This invaluable working hypothesis is a part of our medical theology, however, and the analogy is sustained in the comforting reflection that the every-day man need not understand theology in order to be saved, but must live purely, naturally, and act righteously.

Now, law is intended for sinners; and germophobia does its fine work among the criminal classes—those who get sick, I mean, through wilful or indifferent violation of the hygienic precepts of the physical decalogue.

[1] Read before the Maryland Medical and Chirurgical Faculty, 1893

Speaking with strictly scientific accuracy, man should be a noun of the feminine gender, for women outnumber us, and are our superiors, it seems to me, in a majority of the essentials of true manhood, barring those chiefly which we are accustomed to express in terms of the biceps, diaphragm, and gastrocnemius. Again, the poor woman is often immeasurably the better off in her health endowment and healthful views of life generally than her rich and fashionably disfigured sister with her corset and other luxurious ailments, impeded powers of respiration and locomotion, and consequent dread of exercise: her horror of fresh air and sunshine and her languid interests and sympathies.

Says the author of "The Well-Dressed Woman"—a master book of its kind, showing medical intuitions and masculine logic rarely found on such a theme in the opposite sex—"Gynecology is largely a monument to the follies of woman."

Ely Van de Warker, in the MEDICAL RECORD, February 18, 1893, seems to think so too, and this eminent specialist deprecates the routine use of the speculum, and even the occasional use of the sound, and credits "local treatment" with a large concern in creating the "morbid mental condition" known as "womb on the brain." What are we coming to, may I ask, in our adoration of pathological states and doings in low life generally? "In Germany, the recent graduate too often regards his patient 'as the incidental appendage to a more or less interesting morbid process.' Is the practitioner to take a 'back seat' while the test-tube, the microscopical slide, and other instruments of precision often wielded by mere theorists are usurping his powers and functions? The chemist or bacteriologist is merely an assistant of the true physician. The patient and his personal sufferings are not to be lost sight of, nor will the sick man be content to be regarded as a mere culture-medium or a source of interesting secretions and other specimens" (MEDICAL RECORD). These strictures are certainly entertaining reading for the health specialist and must be his apology for a reappearance in the domain of medicine.

Our contention is, as fully presented by Dr. Welch in his recent lecture before the Sanitary League of Washington, that bacteria are possibly contemporaneous with man: that they confined their attention in the days of our first parents strictly to their own business—the beneficent "breaking-up of highly organized substances and the preparing of food for the higher plants;" that our ancestors knew nothing about them and bothered less, and that we, their degenerate and spendthrift offspring, should store up a little surplus health for our progeny by mending our ways and quitting our civilized foolishness, or the world will be given over to the germs, and man become the lowest of the "lower (?) animals." No tombstone or monument has ever been erected to a mule, for example, because it is a matter of history that none of his tough proud ancestry ever were caught "dead." What must his reflections be as he assists at a funeral in Greenmount, or scans the obituary poetry of the *Sun*, or the rate of colored infant mortality in the District? He knows too well that full compliance with man's civilizing processes would be also death to him, and so in his mulish wisdom remains intractable.

We can't "fool all the public all the time." The same protective instinct shields the masses as it does the animal creation. To the general public there is but one system of medicine, and it is the equal heritage of all honestly purposed, common-sensed, fairly educated practitioners. No school but that of experience confers its degree, and the most successful exponent thereof is he (or she) who most reverences nature and joins to ordinary attainments the faculty of recognizing human limitations and ignorance. Zymotic diseases are chiefly a reproof to the selfishness or indifference of crowded communities—to the amazing and disgraceful ignorance and contempt of health ideas, to personal and municipal laziness and uncleanliness, and to the languid protests of "those who know these things." Science and nature equally preach the doctrine that thorough sanitary work practised by the authorities and by the people will secure exemption from all these forms of pestilence and from many other maladies of which the public stands constantly in dread.

The Washington *Star*, on April 17th, published an account of how a young minister in South London, with six thousand mechanics, mostly poor, in his parish, formed a committee of visitation during the cholera scourge, some twenty-eight years ago, and at a cost of about $250 cleaned up generally every house in a friendly co operative spirit, and kept the cholera in unbroken quarantine, not a single case crossing the boundaries of cleanliness, though many cases occurred just across her borders, where the rector was often called to minister to the dying. It is far better to quarantine the filth and isolate the dirty and the lawless than to keep brave, healthy, cleanly people cooped up in a Normannia twenty days, which savors more of a cholera culture experiment. Von Pettenkofer's and Emmerich's swallowing of the cholera bacillus justifies the assertion that if we can "make ourselves and our homes 'cholera proof,' we need not fear even infected water." Granting that the experiment produced a mild form of cholera in each subject, the brave old scientist, seventy-four years of age, diabetic, without a tooth in his head, and with other infirmities of age, took all precautions to encourage the germs, neutralized the acidity of the stomach, used no medicine during his attack nor altered his diet, pursued his usual avocations, and escaped with some colic and diarrhœa (MEDICAL RECORD, January 28, 1893). He himself admits that his experiment might have had a fatal result if it had been carried out in Hamburg, where the factors dependent on place and time ("local disposition") were different. The editor concludes that "the senseless panic of last fall must not be revived by an appeal to this mental pabulum, even if we do get some cholera this summer. I believe, of course, in "personal immunity" as a term which explains what is quite unintelligible as yet. Why not encourage it to become epidemic, when it might be found to coincide very neatly with personal hygiene and cleanliness, external and internal, or inherited vigor?

One of my professors was an aggravating exempt of this kind, and I have heard it said "he never took anything," contagious, or otherwise, I mean. His neatness and freshness of skin were quite noticeable. He was considered a sort of hygienic crank, of course, and I have a pamphlet by him, entitled "House Air, the Cause and Promoter of Disease," which settles it. The practical and cultured McSherry turned aside from paths of disease to offer the public "Health, and how to Promote It," a literary treat outside of its excellent subject-matter. The elder Chew reasoned of mental health for medical students in true classical form.

Have I forgotten the "poor man"? Oh, no, I have had him in mind all the time. He must play an intelligent, passive rôle first, then a very active one. His needs are principally education, by precept and example. Our present able and energetic Health Department have issued from time to time admirable instructions in print on the care of infants during the hot season, the prevention of the spread of diphtheria, etc. The public cannot too clearly understand that medical science has nothing more valuable to offer than its non-medicinal suggestions, grounded on clinical and laboratory research—health maxims which, as the Paris profligate told his doctor, "any fool knows" something of, and which, I may add, all fools decline to pay for except in bitter personal experience.

Dr. Abbott, late bacteriologist at the Johns Hopkins Hospital (an out-and-out germ specialist, with practical experience, however, as deputy health officer of the port of New York), as a result of observations made at Swinburne Island during last September and October, speaks of the treatment of Asiatic cholera (MEDICAL RECORD, March 25, 1893), after remarking that the cholera death-rate, which on board most of the steamers was over ninety

per cent. of the total number of the sick, was reduced at Swinburne Island to twenty per cent. with further prospects of improvement—urges that opium and all its derivatives, as well as hydrate of chloral, bromides, etc., should be avoided, as depressing the action of the heart and the vitality of the patient. He condenses his therapeutic and germicidal tendencies into the words, "Wash out the blood (to free it from ptomaïnes), wash out the intestines (the localized seat of the pathogenic germ). Protect the alimentary tract from irritation (by rest and careful dieting), use hot-air baths and massage when the temperature of the body needs maintaining—make the nutrition of the patient your principal aim. Any case of diarrhœa in a cholera-infected locality should be considered as suspicious and intestinal lavage with tannin and sterilized water administered. Dr. Alan P. Smith much prefers the use of gum opium to any of its derivatives when quiescence is imperative; and fractional doses of calomel are also of service.

My own mucous membrane, thanks to the abuse of drugs eighteen years ago, would very much prefer small and oft-repeated doses of castor-oil if necessary, abstinence from food until indicated, when hot milk, soft-boiled or raw eggs, some broth made scientifically as by the Atkinson oven, or a moderate quantity of steak or roasted beef, without condiment, are desirable. A few doses of diluted sulphuric acid, combined with a little opium, might assist matters; but nothing, in my judgment, can so naturally and harmlessly meet the chief source of danger, viz., the paralyzed innervation, as the judicious use of hot-air or water baths; favoring elimination, equalizing and stimulating the circulation, and resting and tranquillizing the patient. Dr. Baruch, of New York, has rewritten the old but never-to-be-displaced "Materia Medica," which every young graduate should possess as the coming system of therapeutics—2 vols. of 343 pages, devoted exclusively to "the uses of water in modern medicine." "His chapter on the 'Tub-bath' will be a revelation to many intelligent practitioners who thought that they were thoroughly acquainted with the subject before."

Dr. Billings, in his address on "Baltimore's Needs," before the Charity Organization Society (reported extensively in the daily papers of February 28th), spoke of the necessity for public wash- and bath-houses for the use of the poor, public abattoirs, etc. Dr. McShane's report, previously issued, modestly omits these specific and imperative needs, possibly because he foresaw that other requests, even when granted and provided for, undergo an indefinite stage of financial incubation before being hatched by a well-disposed ways and means committee. As water contamination is the most certain factor in the spread of cholera, so cleansing and refreshing of the individual externally, internally, and eternally by water is one of the most effective prophylactics; and, though not a believer in the "paternalism (?) of the Czar," I do think the municipal fathers owe to the great unwashed a free bath, even if they ask them to furnish the soap and towels. The change it would make in the morals of the community would a hundred times pay for the outlay. Some people would get a chance to see themselves as they had never done before. These baths should be erected convenient to the heart of the crowded communities, as is the case in New York.

That previous attempts to get them here have been futile is a public and private disgrace, and an unwashed stain upon our fair city's philanthropy.

The State must provide means of isolation and sequestration, render localities healthful and keep them so, purify the water-supply, forbid, effectively, overcrowding in districts and houses, and make conscienceless landlords pay dearly for their inhumanity. Official inspection of all food products seems indicated when an expert places the amount of money expended for food adulterants at many millions. Says Dr. Ernst, of Harvard: "The absolute quarantine idea is passing away, though a strict watch on vessels should be kept. To the poor should be secured a more healthy and abundant nourishment, proper shelter, and sufficient clothing. Public instruction of the nature of emergency lectures should be given by every government at the beginning of an epidemic. It should include directions for the general rules of conduct and hygiene, and some advice as to the administration of remedies until the doctor can be reached. Such instruction should also include and lay especial stress upon the necessity for immediate disinfection and destruction of all evacuations and of soiled clothing, and upon the importance of a pure water-supply. Crowds of poor people, oftentimes collected in single tenements, should be scattered." Here is plainly a cry from Macedonia which calls for organized church effort, for the gospel of health goes hand in hand with the gospel of love and peace. Smile if you please, but I offer this tribute of justice to the only religious body which has a slum sanitary corps, so far as I know; I mean the Salvation Army. Probably the Hebrews among their poor do equally meritorious Christian work.

Let the benevolent women of Baltimore open a New England kitchen, a half a dozen of them, and the midday lunchers among the working-classes will bless their memory. This is practical prohibition work and the greatest foe to the saloon curse. Our dietetic customs all want a modern overhauling. Ancient beef-tea has gone to the land of Urea. Professor Voit has broken "the staff of life" by feeding an exclusive bread diet to dogs and rats, and causing dropsy and anæmia. Oatmeal is decidedly too rough on American stomachs and cracked wheat not what it is cracked up to be. Baltimore grits, in my experience, is queen of them all. There is no healthier people than the Hebrews, and they are safe dietetic guides to follow. They are great believers in soups, and know how to make them, too. In this hurrying, nerve-exhausting land of ours, a well-made, nutritious soup is indispensable, more perhaps to the worker with brains exclusively than to the more rational worker with muscles and brains. Good soup is a *rara avis*. The Boston patrons tell the cooks in the New England kitchen that they can do more work on the things they buy there (for a minimum outlay) than after any other expenditure.

In conclusion, if you cannot be perfectly healthy, be as clean and healthy as you can. "By thoroughly hygienic lives, by eating wholesome food, drinking pure (boiled) water, keeping the skin clear by daily baths, changing and ventilating the clothing frequently, sleeping and living in well-ventilated rooms, we may place the system into fighting trim and bid defiance to the invader even if we cannot prevent his entrance into our midst" (*Dietetic Gazette*). Let the choleraphobiac remember 'that the actual swallowing of the cholera poison by men in good health and of good habits did not produce a serious type of the dreaded disease." Shall we restrict immigration? Yes, but only to the "devil's poor." Let God's poor and oppressed and even the "poor devils" of other countries have a chance to make men of themselves in this land of civil and religious liberty. Let the Russian Jew have this chance. He may not become a Rubenstein or a Paderewski (Polish), but he has latent character, possibilities which those who know his antecedents will confidently endorse.

After steamship companies have done their duty by the confiding emigrants whom they often herd and feed like cattle in transitu, freely asserting that they make up by the profits on the steerage what they lose on the overfed cabin passenger; when capital and labor understand their mutual interdependence; when race feeling is a stigma, sex discrimination a disgrace of justice, monopoly a crime, politics synonymous with statesmanship, and honesty the only policy, then the field of medicinal action will have been cleared and there will be nothing left to cure. This humble effort may seem to some a strange blending of things incongruous—religion, politics, and medicine.

Let no man put them asunder.

Speaking solely for myself, but voicing, I am sure, a deep undercurrent of thought and action which is aiming to simplify and cleanse society, there is a panacea for all the evils of the body politic, an unfailing specific for many ills that flesh is heir to, a natural, universal, and facile germicide—

'Tis Brotherhood!

EARLY DIAGNOSIS AND TREATMENT OF POTT'S DISEASE OF THE SPINE.[1]

By GEORGE E. GORHAM, M.D.,

ALBANY, N. Y.

In these days, when medical literature is replete with newly discovered truths, startling facts, and brilliant hypotheses gathered from the fields of study and observation in bacteriology, pathology, physiology, and hygiene; when the surgeon is astonishing us and gaining the admiration of the world by his bold entrance into the deepest recesses and most vital parts of the body, there to remove the offender, whatever it be, close his portal of entrance, and bid nature seal it, which she does speedily, leaving no trace except the cicatrix of primary union; it seems a dull subject for me to ask you to consider the hunchback.

"Pott's Disease: its Early Diagnosis and Early Mechanical Treatment," is the subject I shall try to present in this short paper for your discussion this evening; and to him who shall say, what does a general practitioner know about orthopædic surgery, I answer: I know of Pott's disease that which I hope you may never know; I know what it is to watch the sufferings of an own son, listen to his night cries, and picture to myself a suffering cripple turning to me in after-years and saying, "Father, where was medical science, that a slight bruise should have been allowed to deform me for life?" This knowledge forced upon me, has led me to seek more and to investigate the subject from a general practitioner's standpoint and to prepare this paper, hoping that the surgeons and orthopædists present may by their discussion bring prominently before the minds of general medical men, the great importance of an early diagnosis and proper treatment in the first stage of spondylitis.

According to the pathologists, spondylitis is a pathological condition commencing in the bodies of the vertebræ or inter-vertebral substance as a hyperæmic spot. As the disease advances the spot grows larger and opaque, while hyperæmia surrounds it. Later cheesy degeneration of its centre takes place, or both caseation and suppuration may result, producing bone abscess. Then follows, in the natural course of the disease, a long and varied list of pathological changes; deformity proportionate to the bone destroyed and the vertebræ involved, compression myelitis with resulting paralysis, abscess, pain, emaciation, etc. But it is not within the scope of this paper to speak of these. It is the early diagnosis and mechanical treatment which may prevent such dire results, that interest us to-night.

The cause of this morbid phenomenon is not yet definitely agreed upon. Percival Pott, who first clearly observed and wrote of it in 1771, considered it a constitutional disease, and I believe the idea has prevailed in the mind of the general profession from that day to this, viz.: that it was a local expression of struma or tuberculous diathesis. Tubercle bacilli are found in the diseased tissue, and it is therefore called tuberculous ostitis. That trauma is a frequent cause is freely admitted by all, and by some claimed to be the prime factor. Dr. Lewis A. Sayre says: "I have arrived at the conclusion, based upon an accurate and carefully recorded experience, that it is produced almost always, if not always, by some injury to bone or cartilage, and is hence traumatic in its origin."

Dr. Bradford says: "In short it may be assumed that the determining cause of caries of the spine is jar or superincumbent pressure, the influential cause that physical state which is incapable of resisting slight trauma."

Drs. Morton and Hunt, in their review of the subject published in Sajous's Annual for 1888, speaking of the constitutionalists and localists, state that the localists seem now in the ascendency.

Whatever the cause, whatever the nature of the inflammatory process, it is an ostitis which, as it advances, destroys the bodies of the vertebræ until they are crushed down by superincumbent weight, when the column pitches forward and the kyphosis is produced.

The importance of an early diagnosis can scarcely be over-estimated in a disease so insidious in its attack, and so far-reaching in its destructive work.

It is not an unimportant matter to entail years of suffering and death, or, what is worse, a long life of ill health and unsightly deformity upon one of our fellow-beings; yet this may be done by our neglect to diagnose and properly treat Pott's disease early in its course.

Gibney says: "An experience with deformities extending over a period of twenty years, prompts me to plead at every opportunity for an early diagnosis." He also states, "one would be amazed if he knew how many cases of Pott's disease come for treatment after the existence of deformity;" and again he emphatically states, "the recognition of the disease before any deformity arises is not difficult, provided the physician has accustomed himself to making a thorough diagnosis." This is a polite hint from an acknowledged leader in this department of medical science, but shorn of professional courtesy, it means that we general practitioners, by allowing Pott's disease to pass on to irremediable deformity without proper mechanical treatment, losing forever the opportunity when mechanical treatment might have prevented such deformity, are responsible for many of the suffering hunchbacks we see about us to-day.

Let us take, then, this hint, and review briefly the diagnostic points. The diagnosis after deformity is present can usually be made at sight. Scoliosis, rachitic spine, round shoulders, neurasthenic or hysterical spine, and fracture, are the only things with which it is liable to be confounded. The diagnosis before deformity is more difficult and far more important, but it can generally be made, and when made thus early I know of no condition which will give more gratifying results (considering the gravity of the trouble, of course) to him, who with care and skill, adopts and follows up efficient mechanical and hygienic treatment.

Wherever a diseased process is going on, nature is striving to overcome it; wherever there is deformity or loss of use, nature is trying to compensate for it. The contraction of the muscles with flexed thigh in hip-joint troubles is not the disease, but nature's effort to protect the joint by fixation. The hypertrophied and throbbing heart is not the disease, but nature's effort to compensate for an imperfect valve. So in spondylitis, long before kyphosis is present nature is making her efforts to protect the inflamed tissues. If, therefore, we observe her closely and interpret correctly, we shall be able to locate the disease and learn, too, a valuable lesson concerning treatment. As in the hip-joint, so in the vertebræ, nature, true to herself, contracts the muscles and produces rigidity of the portion of the spinal column involved. The child's efforts to further protect the diseased bone from jar and motion may also be observed, and to these are to be added night cries, spasmodic pains, aggravated by motion, in the abdomen, the chest, occiput, or wherever there is a terminal end of a nerve which has its origin near the seat of the disease. A grunting respiration and lack of endurance are commonly to be found. Lateral deviation of the column and elevated temperature are also common symptoms before the angular curvature is present. A child having any one of these symptoms mentioned, the cause of which is not definitely known, should be carefully and thoroughly examined and re-examined until, if possible, a positive diagnosis be made;

[1] Read before the Albany County Medical Society.

and if it cannot be made, the child should be confined upon its back until spondylitis at least can be excluded.

The rigid spine is to be detected by removing all clothing and observing closely the child while walking, standing, and bending to the floor. If spondylitis be present, the child will walk guardedly and carry the spine stiffly erect or bending backward, often placing the hands upon the hips, thus transmitting the weight of the body to the pelvis. While standing he will rest his hands upon some near object for the same purpose. In sitting he will relieve the inflamed tissue in the same manner by bearing his hands upon his chair. In bending to the floor, he will flex the legs and not the spine, or at least not the diseased portion. To further examine for rigidity of the column, the child should be laid prone upon a couch or table, and then, while the patient's legs are extended, the surgeon grasps the ankles and lifts the body. If Pott's disease be present in the dorsal or lumbar region, the muscles of the back will be so contracted that the whole back will come up like a stiff board. If in the cervical region, the muscles of the neck will be stiffened, causing a noticeable stiff neck and peculiar carriage of the head when the child stands. In bending the column backward by lifting, one must be familiar with the flexibility of the normal spine, and also know that the flexibility varies in different patients. The grunting respiration cannot well be overlooked, and Dr. Sayre advises placing the child across the lap and then separating the knees until the body of the child is extended, or until all pressure is relieved from the diseased bodies, when the child will often breathe deeply, giving, as it were, a sigh of relief.

The night cries are very significant. They are not the frightened cry of what is called night terrors, when the child awakens in a fright, but a sharp cry of pain, and with it an effort is made to get relief by changing the position, which will be done very guardedly.

The hip-joint and the spine should always be examined when these cries continue for any length of time. The abdominal, thoracic, and occipital pains should also excite suspicion, and if their cause is not known, that portion of the column near the origin of the nerve whose distal end is crying "I am in trouble," should be carefully examined for rigidity. Pain at the seat of disease is said to be seldom present.

Bartow, of Buffalo, was the first, I believe, to call special attention to lateral deviation of the spine as almost a constant early symptom of Pott's disease in the dorsal or lumbar region. Lovett, of Boston, after a very carefully conducted examination of many cases, confirms this statement. This lateral curvature is most readily detected by viewing the body from the front, and, like the rigidity, is caused by voluntary or spasmodic contraction of muscles. Lovett also found, after a long series of observations, that there was an evening exacerbation of temperature of from one to three degrees in acute Pott's disease, and this too without abscess formation.

A child with Pott's disease is a sick child, and it will be found on inquiry that it is not playing as much or as vigorously as usual, is not sleeping as soundly, and is irritable.

It will be seen then that, according to careful observers, the most significant signs of Pott's disease before angular curvature is present are: rigidity of the spine, neuralgic pains, lateral curvatures, high temperature, grunting respiration, impeded locomotion, peculiarity of gait and carriage, night cries, and a general ill condition.

With these points in mind, and remembering the pathological conditions which must exist before the angular deformity is produced, viz., inflammation, ulceration, and destruction of bone until the bodies crush down one into the other, the diagnosis in most cases is not difficult. To give the differential and regional diagnosis would extend this paper beyond the time allowed me.

I have spoken only of the early diagnosis, and according to the title of this paper, will speak only of the early mechanical treatment. Suppose we have, after a careful investigation, found it necessary to convey to an anxious mother the unwelcome intelligence that her child has Pott's disease, what shall we do? Consider it a constitutional disease, advise constitutional treatment, administer consolation, and wait to see if deformity results? There comes a time to every surgeon when, if he waits, a life is lost. There is a time when, if the oculist waits, he dooms a patient to a life of total darkness. The obstetrician may, by inaction, sacrifice the life of mother and child. The responsibility resting on the general practitioner with his case of Pott's disease is not less; his inactivity is attended with no less grave results. To allow a patient to go with a broken arm until deformity is unsightly, and then send him to a splint-maker, would be as sound treatment as to wait until deformity is present in Pott's disease, and then send the patient to the instrument-maker.

To the question, what shall we do? I answer: Explain fully to the mother the nature and course of the disease, and paint the picture dark. Then tell her that complete rest to the inflamed tissue for a sufficient length of time will, in all human probability, if faithfully carried out, allow nature to restore her child without deformity. Make her understand it. Gain her hearty co-operation, and then proceed to treatment.

Promising too much? No, sir. The favorable results obtained by proper fixation of the spine in cases already advanced to destruction of bone, deformity, and abscess, will warrant us in saying that, in the stage we are now considering, we may reasonably hope for a complete recovery without deformity. Good authority in orthopædic work will bear me out in this statement. I have seen it in my own practice. On this point allow me to quote Hilton, in his admirable work, "Rest and Pain." He says. "I trust I shall not be thought too sanguine when I assert it to be my firm conviction that if diseases of the spine were recognized sooner than they usually are (and I am confident they may be), most of the cases would be cured by properly applied rest." Bartow, of Buffalo, says: "Viewing the completeness of recovery which commonly follows efficient treatment in the early stages of Pott's disease, one is strongly inclined to regard the tuberculous process at this period somewhat as a benign matter. That is to say, more importance may be attached to the functional use of the affected vertebræ and the mechanical force which is thereby exerted upon the inflamed bone for promoting the extension of the disease than to its inherent tendency to invade new tissue." So far, then, as treatment is concerned, we have to deal with a traumatic inflammation of the spine.

"Rest to inflamed tissue is surgical law." Therefore, to provide rest and protection to the inflamed vertebræ in that manner which will least interfere with the comfort and well-being of the patient, is the mechanical problem presented for solution. Just in proportion to the caries of the bodies is the kyphosis, therefore, proportionate to our saving the bodies from the destructive ostitis, will be the prevention of the deformity. Pardon me if I here emphasize the fact that it is the carious bodies we are to treat, and not the angular deformity produced by the projection of a sound spinous process.

To secure rest to a diseased vertebra, we must relieve it of its duty of sustaining the column above and protect it from jar and motion. If in a column of bricks the central one is crumbling, and we wish to relieve it from superincumbent weight, there is no way to do it and preserve the relative position of the bricks equal to placing them on a horizontal plane. What is true of bricks is mechanically true of a spinal column. Therefore, if we place a child afflicted with spondylitis upon its back and fix it there with slight extension, we have complied with a mechanical law and done all, and more than can be done in any other way, to provide rest to the carious spine.

Whether this meets the second condition of the problem, in contributing most to the comfort and well being

of the patient, is a question yet undecided. It is held by most men that continued recumbency does not, and therefore, ambulatory apparatus and Taylor's brace, and Sayre's plaster jacket, or their modifications, representing the best mechanical genius of the age, are usually applied except in the very acute stage, or when from any cause the patient cannot stand.

The advantages of recumbency are readily seen. It is always at hand. It can be skilfully applied without the experience and expense necessary to properly apply ambulatory apparatus. It gives rest to the child at once, relieves as nothing else will all superincumbent weight. It insures the child against accident from falling, and against further traumatism to the diseased tissues. It prevents deformity in the cervical region as no other treatment will, and it is the only treatment which can be fairly claimed to produce recession of the angular deformity after it has occurred.

That recumbency is mechanically more nearly correct than any other treatment, admits of no discussion. Relieved of its objectionable features, confinement and lack of exercise, it fulfils every requirement for complete mechanical treatment of spondylitis. I have therefore adopted recumbency for the treatment of my cases, and tried to do what I could to overcome its objectionable features, and I have to show you the apparatus which, so far as I know, is novel in some of its construction and details.

. . . . . .

Case I.—E. B——, two years of age. I saw him in October, 1878. He had walked with difficulty during the summer, had been fretful, wakeful at night, and cried when lifted. His trouble was considered rheumatism, and for it he had been treated. On a careful examination I found rigidity of the spine, and a small knuckle in the middle dorsal. A Taylor brace was carefully fitted and the child kept in recumbency most of the time. He was given pure cod-liver oil and phosphate of lime. This treatment was continued for two years, gradually allowing the child to be on his feet. He made a complete recovery without deformity. He is now in the Boys' Academy, and was one of the successful competitors at the last military drill.

Case II.—M. B——, two years of age, whose mother had died of phthisis, was seen in April, 1890. She had never walked, and for six months was unable to sit. She was lying in her cradle with spine bent at an angle of forty-five degrees in the middle dorsal region. The greatest encouragement which had been offered was that she would live but a short time. A Taylor brace was fitted, and the child was kept in recumbency without fixation or extension for four months, when she was allowed to go about the room. In July last, a plaster jacket was applied, which she still wears, suffering no pain, and runs about at her play happily as any child. She is well nourished, and save from her deformity, which of course cannot be corrected, she seems well.

Case III.—T. G——, born December, 1888; family history good; fed artificially; walked at fifteen months, and was allowed by his nurse to run to and from the street car for two blocks, over a stone pavement, occasionally falling over the curb. He soon developed a limp and night cries. Hip-joint disease was recognized, and he was placed in an ordinary crib with extension to the leg. The extension was continued with more or less irregularity, I am sorry to say, for a year, when a sharp knuckle at the level of the first dorsal vertebra was noticed. He was kept recumbent for another year with extension to the leg and head, with the same irregularity in treatment, when in February, 1892, I brought the child to my own house, and began treatment by fixed recumbency, with extension and counter extension. The child at this time was emaciated; his temperature was 100° F. at night, and he had night sweats. The thigh was flexed and fixed by muscular contraction at an angle of forty-five degrees. There had been compression myelitis with paralysis, which had passed away, but had left marked contractions of the tendons and muscles of both legs. His sleep was disturbed by frequent spasms of pain in the hip, occasioning the hideous night cries, and whenever moved severe pain was induced. In this condition, I placed him in my improvised recumbency apparatus, which I will presently show you. His pains and night cries soon ceased; he gained in flesh, the temperature became natural or nearly so, and he has been happy ever since, in his fixed recumbency, without interruption. The hip-joint has quieted down; there are no more spasms; the leg lies nearly straight, the foot being elevated three inches. The spine is consolidating with no noticeable deformity, and the boy is well nourished, and he looks as well as the average boy of his age.

Case IV.—J. M——, five years of age, came to me in April, 1892. When three and a half years old, or eighteen months before I saw him, he fell and injured the spine in the lower cervical region. For a year he ran about, suffering much pain, with greatly disturbed sleep. A compressed myelitis followed, producing motor paralysis of the legs, which had existed from December, 1890, to April, 1891, when I first saw him. I placed him in fixed recumbency with extension to head, with immediate relief from pain, and he slept soundly the first night, for the first in over a year. He was given extract of malt with cod-liver oil and phosphate of lime. He slept well every night, was happy during the day, and gained rapidly in flesh. The paralysis improved in three months' time so that he could move the legs freely, and bear his weight on his feet. In October, he was taken from his bed and placed in a go-cart, extension to the head being continued, and allowed to go about the house. He is now about the house at play, going up and down stairs, with no support except a large collar to sustain the head.

Case V.—Baby B—— was brought to my office from fourteen miles out in the country, July 26, 1892. He had made the same journey frequently during the summer to get relief from constant worrying, sleeplessness, and crying. I suspected spondylitis at once from the characteristic grunting respiration. The marked rigidity of the spine and a slight knuckle in the upper dorsal region confirmed my suspicion. I directed the father, a poor farmer, to make a little frame of pine boards, two inches wide, set on edge, and cover the top with strong canvas; to place the child on the canvas with small sand bags at either side, and with broad bands to bind the child and sand bags to the frame. I ordered cod-liver oil, ten drops, three times a day, and tablet triturates of phosphate of lime. Not hearing again from the child, I wrote the following letter which will explain the result:

"Albany, N. Y., December 23, 1892.

"Dear Sir: Will you please write me within a day or two how the baby is, and just how you are managing with him? Do you keep him down thoroughly all the time? Also answer the questions on the paper I send.

"Hoping you are doing well with the boy, I am,

"Very truly yours,

"Geo. E. Gorham."

1. When did you first notice anything wrong with the child? About the first of March, 1892.
2. How old was he then? About six months old.
3. How did he act? He cried and worried.
4. How much did he cry? About all the time.
5. How much did he sleep at night? Not much of any.
6. How much in the day? Short naps.
7. When did I first see him? July 26th.
8. When did you first see the bunch on the back? Only a few days before you saw him first.
9. How much relief did he get from being put down, and how soon? He got relief immediately.
10. What did you think the baby weighed when I first saw him, on July 26th? I think about fifteen pounds.
11. What does he weigh to-day? Twenty-five pounds.
12. When was he born? September 11, 1891.

13. How much pain does he have now? Not much if any. He cries once in a while.

14. Does he grunt when he breathes now, as he did last summer? The grunting has disappeared. I will be in in a few days, as you wanted me to be in about Christmas. The child eats and sleeps well; he has grown over one inch since you have seen him last.

Yours truly,

R. B.

REPORT OF A CASE OF MYXŒDEMA.[1]

By W. GILMAN THOMPSON, M.D.,

NEW YORK.

The patient is L. S——, female, aged forty-four, single, born in the United States, by occupation a housekeeper. Her father died of apoplexy, her mother of heart disease, and a brother of phthisis. The patient's history is unimportant up to twelve years ago, when symptoms of the present disease first appeared. Menstruation has always been normal, and the menopause has not yet been reached. About twelve years ago, while living on Long Island, the patient suffered considerably from malarial fever, having repeated attacks during a period of two years. Shortly after the ague commenced she noticed that her face was becoming swollen, especially about the forehead and eyes. Soon she became weak, nervous, and very drowsy. The skin was dry and pale. Food distressed her, and she had unusual susceptibility to cold. Alopecia followed, and the patient observed some clumsiness in moving about, with great fatigue on physical exertion. These latter symptoms all developed within a period of three or four months, and have slowly increased in severity. Salivation has been occasionally present, and for a year or more the patient has been unable to sew or read for any length of time on account of excessive lachrymation, although vision is normal. There has also been occasionally partial deafness, and tinnitus aurium, attributed to taking cold. Recently palpitation has been a frequent and annoying symptom. Two years ago speech became somewhat slow and difficult, and the patient thinks that her memory has failed considerably. No depression of spirits. There has been recent slight swelling of the feet and legs, which have also often felt numb and cold. Slight dyspnœa, constipation, and anorexia have also been present.

Examination on admission to the Presbyterian Hospital, April 5, 1893: Patient fairly nourished, anæmic, skin everywhere dry, loose, and inelastic; desquamation universal, but most marked on the legs and chest, where the skin is peeling off in large flakes resembling those of scarlatina. Hair absent in axillæ, very scanty on pubes, and very thin, dry, and brittle over most of the scalp, especially anteriorly and toward the vertex. Slight œdema of both legs. Face swollen, having peculiar waxy, doughy appearance. Lips thick; naso-labial fold obliterated; eyebrows arched; nose flattened; tongue greatly swollen, to the extent of half an inch at the tip. Speech thick and hesitating. Moderate salivation. Gums swollen and bleed readily. Hearing and vision normal. Mind apathetic. No visceral lesions apparent. Heart sounds distant; no valvular murmurs. Patellar reflexes diminished. Gait slow and labored. No retardation of tactile sensation. Pulse, 104; respirations, 20; temperature, 97.8° F. in mouth. Blood: Hæmoglobin, seventy-five per cent; red disks, seventy-seven per cent. (on a basis of five million per cubic millimetre). The thyroid gland cannot be distinguished through the tissues of the neck.

Treatment.—After keeping the patient for four days under observation, without treatment, she was given daily doses of five minims of a glycerine extract of the sheep's thyroid gland, prepared for me through the kindness of Dr. George W. Crary. The temperature was then taken every two hours, and careful observations were made with reference to any reaction. As none followed, the quantity of extract given was increased by one minim with each dose, until a week ago the patient was taking twenty minims three times a day. The patient has now been under treatment for fifty days. During this time the temperature has fluctuated three degrees, ranging between 97° and 100° F., most of the time being subnormal. At first the daily fluctuations amounted to 2½° or 3° F., but of late they have been only 1° F. The hair has continued to fall out, but the extensive lamellar desquamation has ceased, and the skin in some situations, notably over the hands and arms, has become more elastic, softer, and much less dry. Ten days after the treatment was begun the swelling of the face, especially about the eyes, decidedly diminished, and the lips and tongue became slightly thinner. The patient's mental condition also improved considerably. The feeble circulation has not improved, but the patient sits up daily and moves about the ward. There has been a slight increase in the daily production of urea. Her family and several physicians who have seen her only at infrequent intervals, unite in declaring that there is a positive improvement both in activity of mind and in facial expression. Seen from day to day the change is less noticeable, but the photographs which I herewith present offer favorable testimony. The first was taken before treatment, and the second was taken three weeks after treatment was begun. Several times the extract has been given hypodermically in five-minim doses; but no reaction followed.

Dr. George W. Crary has kindly given me the following notes in regard to the preparation of thyroid extract which he made for me:

"The strength of the extract represents twenty-four grains of gland-tissue to one drachm of glycerine. Strict surgical cleanliness is observed in all steps of the process; boric-acid solution being, however, the only antiseptic used

[1] Read before the Association of American Physicians, at Washington, May 31, 1893.

—heat sterilization being employed. The glycerine is Schering's, twice distilled, and is sterilized before being used. The glands are cut up separately, and those diseased are of course thrown out. After standing four days, the extract is ready. After two months it seems to lose something essential, and I do not now use any older than that."

The patient received no other medication than the extract of thyroid gland at any time.

Clinical Department.

A CASE OF ABSCESS OF THE LIVER—OPERATION—RECOVERY.

By WILLIAM W. GOLDEN, M.D.,

ELKINS, W. VA.

On March 4, 1893, I was called to see Mr. A. C. D——, who gave me the following history: On January 24, 1893, he was taken with a severe attack of diarrhœa, consequent on the ingestion of a few glasses of cider. He since then failed in all his efforts to re-establish a normal physiological condition of his bowels, which he previously always enjoyed, suffering most of the time with alternating diarrhœa and constipation, accompanied by annoying flatus. At the same time he noticed a gradual failing of his health, which he could not sufficiently account for by the mere intestinal disturbance. His appetite and gastric digestion continued within fairly normal limits. The increasing debility finally compelled him to keep his bed part of the time. On February 2d, during some careless exertion, he was suddenly taken with a sharp lancinating pain through the upper region of his abdomen, followed by a strong tonic spasm of his recti abdominalis, which "doubled him up," and held him in an almost immobilized condition for several days. By February 12th he felt almost entirely free from the pain, and the muscles had relaxed. By this improvement he was tempted to leave the bed, and made an attempt to stir about and attend to some housework. But on trying to lift up a heavy log to place it on the fire-grate, he felt as if something broke loose in his abdomen, in the region of his liver, imparting a distinct sensation of tearing. He was since then obliged to keep his bed all the time. A soreness, continually increasing in severity, developed over the hepatic region, extending also below it.

On February 25th he noticed a slight bulging of the epigastric region, close to the right ninth costal cartilage. His health was now more markedly failing. He had fever and occasional chills and sweats, also a hacking cough. Constipation became still more obstinate, and the tympanites was greatly annoying. On the day of my first visit I found the following signs and symptoms: A bulging of the epigastrium, about the size of an adult parietal bone, about one-third of it extending to the left of the median line and the rest to the right of it, reaching above and to the right the free border of the right ribs, and below to a point about two inches above the umbilicus, extending for a short distance into the right hypochondrium. At about the centre of the bulging the skin looked somewhat reddened and much stretched, but not adherent. Palpation revealed indistinct fluctuation, and showed that the visible limits of the bulging did not correspond to the limits of the underlying mass producing it, as it extended for about an inch more in all directions (save at the border of the ribs where this could not be determined for obvious reasons), and to a depth beyond the reach of the palpating fingers. The mass was immovable by manipulation, but moved up and down in the long axis of the body with the respiratory movements. The liver was enlarged and the heart was displaced upward. The pulse was weak and rapid (110) and irregular. He felt cold in the lower part of his body, and unusually hot in the upper. Oral temperature 103° F. Gastric disturbance was present, but not very marked. In spite of the free use of cathartics and copious enemata and enteroclysms no evacuation could be produced (the injected water being retained) unless the patient assumed an attitude approaching the knee-chest position. Emaciation was considerable.

I could find but one rational pathological explanation to all these clinical phenomena, viz.: That the intestinal derangement he suffered from at the very beginning of his illness resulted in the establishment of an ulcerative process. Some of the morbid products, loaded with pyogenic bacteria, were swept off into the return circulatory current through the portal vein to the liver, where they halted and excited an acute circumscribed suppurative hepatitis. It then extended to the surface, having the capsule of Glisson for one of its walls. By the careless exertion made on February 2d, the capsule gave way, and the escape of pus excited an acute peritonitis, which, thanks to the absolute rest provided by nature's inflexible splints—pain and muscular spasm—remained local, having become circumscribed by the formation of new tissue. The same had recurred on February 12th, under the heavy strain of lifting. The result was a mass of purulent matter contained within a cavity formed partly by the parenchyma of the liver, partly by dense connective tissue, and partly by the anterior abdominal wall and its lining peritoneum. The obstinate constipation and the circulatory disturbance in the lower half of the body were mainly due to pressure upon the intestines and abdominal aorta. Having thus formed the diagnosis of abscess of the liver, I explained to the patient the nature and probable termination of his affection and urged an operation. He hesitated at first, but after a few days more of suffering he consented. With the valuable assistance of my friend Dr. O. Hoffman, of Thomas, W. Va., I undertook the operation on March 11th. After thoroughly cleansing the field of operation Potain's aspirator was applied, but it was not till the largest needle was introduced that the contents began to flow. The fluid thus drawn off was creamy, yellow, largely mixed with blood, and showing a greenish tinge here and there. Its odor was horribly offensive, such as I have witnessed only in long-standing empyemas. As the patient was strongly prejudiced against anæsthesia, and as his general condition was also thought rather contraindicating it, this was omitted. Cocaine was then injected and an incision was made through the abdominal wall, about three inches in length, across the centre of the tumor, parallel with and at a distance of about one and one-half inch from the lower border of the right ribs. A broad stream of purulent and bloody matter kept on running for about half an hour under gentle pressure. The whole quantity that escaped was estimated at about four pints. The abscess cavity was then irrigated with bichloride, followed by a one per cent. solution of creoline. A probe about five inches long could not reach the bottom of the cavity, striking only a number of trabeculæ stretched across the cavity in different directions. The cavity was then loosely packed with iodoform gauze and a strictly antiseptic dressing was applied. The patient bore the operation comparatively well. His temperature rose about two degrees F. immediately after the operation, but soon came down to normal. All pressure symptoms quickly disappeared, and the marked relief felt had the best possible tonic effect on the patient. The dressing was changed on the third day, when about sixteen ounces more of purulent matter was washed away. The subsequent history of the case was entirely uneventful. The cavity kept on filling up rapidly, and he gained in strength and flesh under a nourishing and stimulating diet. On April 3d he left the bed, and on the 6th he was able to be transferred from his farm to the town of my residence, a distance of about thirty miles, partly by rail and partly by country road. When the cavity had filled up entirely I allowed the external wound to heal up. On April 22d I discharged him, cured.

Remarks.—Abscess of the liver, though not very rare, is yet by no means very common. Out of two hundred and fifty-one autopsies made at St. Luke's Hospital, New

York, there were only nine cases of hepatic abscess. It now enjoys a somewhat more liberal etiology, tropical dysentery being only one of its causes, though the most frequent one. There was a case at Bellevue Hospital, New York, which resulted from the penetration of a fish bone through the lower portion of the œsophagus into the liver. The symptoms are not always clear, but, when fully developed are unmistakable. The gastro-enteric disturbances may be the primary cause of the abscess or they may be the result of mechanical pressure by the abscess, or of deficient secretion of bile, or of both. In my case the gastric symptoms were not marked. In the treatment a free incision is imperative. Had I not done it my conscience would never be clear. Aspiration alone would have only delayed the evil day.

COMPLETE INVERSION OF THE UTERUS—TREATMENT BY ABDOMINAL SECTION.

By T. M. McINTOSH, M.D.,

THOMASVILLE, GA.

Mrs. J. W. B——, of Camilla, Ga., aged twenty-four, a rather pale, delicately formed, educated, and refined woman, of nervous temperament, was sent me by Dr. Cull, last March, with the history that in December, 1892, she was delivered of her second child. The labor was normal, except that after the expulsion of the head, the uterus ceased to contract and the child remained thus partially delivered for "fifteen minutes." There was then one violent expulsive contraction which brought both child and placenta together.

An examination was not made, as all seemed to be well. The recovery was slow, and the presence of a continuous bloody discharge led to an examination after the lapse of six weeks, when the inversion was found. There was no decided effort made to reduce the organ. The symptoms were dragging pains in the back and pelvis, and the continuous bloody discharge. The patient could walk about most of the time, though with discomfort. The bed and chair were most comfortable, and her health was growing more and more feeble.

On April 2d, the patient was chloroformed, and with competent assistants an attempt was made, for an hour and a half, to reduce by taxis, after the various recommended methods, with absolutely no progress. The cervix uteri was rigid and unyielding. The perfect futility of this effort was thought to eliminate any hope of reduction by elastic pressure or massage, and a repetition of taxis.

On April 13th, an incision two and a half inches long was made in the median line, the operator being between the legs of the patient, whose buttocks were well over the edge of the table, each foot resting on a small table behind the operator. One hand was carried into the vagina and the inverted uterus was raised and pushed through and out of the incision. The blades of an ordinary uterine dilator were then passed into the inverted cervix (the peritoneal side I mean), and the blades were dilated fully. This not being found sufficient, a Farabœuf bone forceps was passed in and the handles supported by an assistant. This dilatation was repeated from time to time during the progress of the replacement, as there was continual recontraction of the resilient cervix. This dilatation was aided at times by the fingers of myself or assistants, pressing downward at the same time on the counter-pressure of the hand in the vagina. The progress of replacement was slow. When the fundus had been pushed upward to just within the lips of the os externum, which would prevent lateral slipping of the fingers from the fundus, a piece of gauze about three inches long, folded several times, was doubled endways and grasped by a long, fenestrated, and toothed Péan forceps, at the doubled end, and the free ends were spread out laterally, thus forming a firm head, as it were, to the forceps.

This was carried into the vagina against the fundus, and the uterus was pushed upward as far as possible and fixed firmly in position, by pressing the lower end of the forceps backward against the coccyx, and the upper end forward against the pubic bone. My free hand, or that of an assistant, was then used in making pressure downward, laterally and rotary, by grasping the uterus fully with the palm or the fingers as dilators and tractors combined. With much fatigue to myself and assistants, the reduction was accomplished in an hour.

Hemorrhage, from a laceration of the peritoneum over the fundus, required a deep suture of fine silk to restrain.

The temperature on the afternoon of 12th (the day of operation) was 100.3° F; 13th, A.M., 99.3°; P.M., 100°; 14th, A.M., 99.3; P.M., 99 4°; 15th, A.M., 99.4°; P.M., 100°; 16th, A.M., 98°; P.M., 100°: 17th, A.M., 98°; P.M., 99 4°. From this date it was normal, and recovery followed without interruption. The text-books recount the theories as to the causes of inversion of the uterus. They record cases of its occurrence in the virgin uterus.

The treatment according to the books is reduction by taxis, and failing in this, amputation, some advising abdominal section. Unless the woman is beyond the child-bearing age, amputation should not be thought of. The aim of surgery is preservation, not mutilation. With sterilization (asepsis) the abdominal operation is but little, if any, more dangerous than amputation.

Cases of complete inversion are rather infrequent, and for this reason the report of this case may be of interest.

AN OPEN SAFETY-PIN SWALLOWED.

By DANIEL F. SULLIVAN, M.D.,

HARTFORD, CONN.

On June 6th I was called to a child, aged fifteen months, who was suffering keenly, and from its expression and gestures the trouble was located in the stomach. All symptoms pointing to functional or organic trouble were absent, and I prescribed, feeling certain that in a little time all trouble would disappear. For three days the paroxysms of pain continued with exacerbations, and but temporary relief given by treatment.

The parents thinking some grave disorder impending desired a consultation.

A diagnosis of teething was made at once by my learned frater medicinæ. For two weeks I was a most unwilling worshipper of that fetich "teething," when suddenly, one morning, after a good dose of equal parts of olive- and castor-oil had been given to the little patient, the mother noticed something protruding from its rectum, and found it to be a small silver safety-pin with bar open. Thus was cleared up the mystery of a long-lost silver pin, and the convenient theory of teething was sustained.

A UNIQUE CASE OF ANGIO-LIPOMA.[1]

By THOMAS H. BURCHARD, M.D.,

NEW YORK.

In March last Dr. —— asked me to examine a swelling he had discovered that day on his back. Upon examination a soft, uniform, semisolid tumor, the size of a Messina orange, was found in the left interscapular space, extending from the fourth to the last dorsal vertebra. The tumor was freely movable and not specially sensitive to manipulation. It not only presented unmistakable fluctuation, but pressure made upon it by the palm of the hand caused its complete disappearance beneath the body of the scapula. Upon removing the pressure the swelling returned. There was no history of recent swelling or traumatism. The diagnosis of cold abscess was made. The tumor was also examined by Dr. H. H. Hagar, and by Dr. L. H. Heneberger, U.S.N., and this diagnosis was confirmed by them.

[1] Reported at a meeting of the North Western Medical and Surgical Society, June 21, 1893.

A few drops of a four per cent. solution of cocaine was injected and the supposed abscess was incised. A drop or two of dark blood, but no pus, escaped. Introducing my finger into the wound a curious and complicated mass of varicose veins bound loosely together by a stroma of fatty tissue was found. The doctor was etherized and the incision enlarged. The tumor was composed almost entirely of enlarged veins, and to the eye resembled a classical angle-worm eel-bob. There was no hemorrhage to speak of, and after the usual antiseptic precautions the wound was closed by seven interrupted sutures. These were removed on the fifth and sixth days, primary union having been secured.

Owing to the curious and deceptive character of the tumor, it was sent to Professor Herman M. Biggs for microscopical examination. The following letter explains itself:

"Health Department, 301 Mott Street,
"New York, May 20, 1893.

"Dear Dr. Burchard: The report has been somewhat delayed because of the nature of the specimen. The tumor is a very peculiar one, unlike any I have ever seen before, but, I think is a benign growth and is to be classed as an angio-lipoma. It is composed entirely of extremely vascular adipose tissue The vessels are both abundant and large in size. . . . .

"Very sincerely,
"Herman M. Biggs."

At my request the doctor has furnished the following history of this curious growth. Twelve years ago he was thrown from a horse against granite steps, receiving the force of the fall on his left side behind the scapula, this also being the location of the tumor. Some ribs were supposed to be broken at this time, but after a few days in bed his back gave him no trouble for a number of years.

During the past five or six years he has had a great deal of sharp neuralgic pain in the front of the left chest, and the left shoulder has tired very easily. The discomfort would be increased by exercise. At first the neuralgic pain was only noticed on awakening, but latterly it would come on at any time and has been much more severe. Not infrequently the pain has been so severe as to waken the doctor from sleep and to keep him awake for hours. Latterly the breathing has become affected from the pain, so that severe dyspnœa would result. Two days before the operation the pain was so severe as to be agonizing. It was at this time the tumor was discovered. Never before had any local swelling or tenderness behind been noticed. Since the operation there has been an entire absence of all pain. Occasionally the shoulder tires somewhat easily.

Points of interest in the above case:

1. The long time that has elapsed between the original injury to the back and the discoverery of the tumor. Twelve years, I admit, is a long time to trace positive connection between the fall as a cause, and the tumor as the effect, of the injury then received. Still, the peculiar anatomical make up of the growth warrants this conclusion.

Undoubtedly the enlarged and complicated venous net-work that constitutes the bulk of the tumor began in dilated and congested capillaries, that went on enlarging year after year, until their present extraordinary size and condition were attained.

2. The severity of the pain and the fact that it was referred to the chest and not to the back. During the last year or two the pain at times has been excessive—the doctor says "agonizing." Its being felt in the chest is a striking illustration of the old law—that pain is experienced at the distribution, and not in the course, of the nerve.

3. The deceptive character of the tumor, presenting as it did well-marked fluctuation and imparting to the fingers the soft, elastic sensation characteristic of encysted fluid.

4. The entire disappearance of the tumor, apparently, under the scapula, when pressure was made upon it.

5. Its peculiar histological characteristics, as found by Dr. Biggs.

6. The entire disappearance of the pain after the removal of the tumor.

7 East Forty-eighth Street.

A CASE OF HYPOSPADIA, CRYPTORCHIDISM, AND ECTOPIA CORDIS.

By J. ALEXANDER MOORE, M.D.,
Helena, Mont.

I was recently consulted with regard to the construction, for purposes of convenience in urination, of a penile urethra, in the case of a child. The subject is ten and a half years of age, has never had any grave disorder and is well nourished and bright. On examination, the empty scrotum is almost perfectly divided by the raphé, and the urethra ends at about its middle. Scalding of the penis by the urine gave a practitioner an excuse for removing, by ligature, the greater part of the organ, which the mother says was about one inch in length and subject to erections. At present the stump does not project from the body more than three eighths of an inch. The testes cannot be discovered. The question of hermaphrodism having arisen, rectal touch with a sound in the bladder disclosed nothing foreign to the male, and the general form and appearance are those of a boy. I could promise no advantage to be gained by a plastic operation.

The normal heart, liver, and cæcum, were found on the right side, and the spleen and stomach on the left. The rule in dextro-cardia, or ectopia cordis, is, I believe, that there is likewise transposition of the abdominal viscera, and this is the first exception I have seen.

SILKWORM-GUT IN THE TISSUES FOR NEARLY THREE YEARS.

Dr. H. Speier, of Duluth, Minn., writes: "On July 22, 1890, I performed an operation for lacerated cervix, using silkworm gut for sutures. On June 22, 1893, I removed one of the sutures which had been overlooked and left for two years and eleven months. It gave no discomfort until quite recently, when the woman felt a sharp pricking produced by the ends, which were cut off quite close to the knot. The specimen removed is firm and hard, and differs in nowise from a fresh specimen."

A Libel on the Extra-Uterine Fœtus.—In discussing the question as to the best period for surgical intervention in cases of extra-uterine fœtation, it is generally assumed that the fœtus is, in the language of the theatre, "a person of no importance," partly by reason of the alleged greater claim to existence of the mother, and partly, also, it may be supposed, because such fœtuses have been authoritatively stated to be usually deformed. Mr. Lawson Tait, who has probably seen more of these unlucky little wights than any other living surgeon, enters a formal protest against this certificate of malformation, first, because, he says, it is not true, and secondly, because, even if true, it does not vitiate their claims to existence when this can be conceded without the manifest sacrifice of the maternal life. Fortunately, it seems possible to reconcile these conflicting interests, and instead of, as has but too frequently been the case, killing two birds with one stone, timely intervention may enable the surgeon to preserve the child and to protect the mother. The present tendency of skilled opinion is decidedly against the unwarrantable delay which over-cautious surgeons insist upon as a preliminary to operative interference; a delay which is the death-warrant of the fœtus, without, we are assured, any corresponding advantage to the mother.—*Medical Times and Hospital Gazette.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, August 5, 1893.

INOCULATION FOR THE CURE OF CANCER AND SARCOMA.

CONSIDERABLE has been written regarding the value of inoculation of erysipelas for the cure of sarcoma and cancer, and some very striking instances of improvement or cure have been reported. The whole subject has been reviewed, and an important contribution from his own experience made, by Dr. William B. Coley (*American Journal of the Medical Sciences*, May, 1893). This surgeon gives details of ten cases of his own, and collects other cases to the number, altogether, of thirty-eight.

Of these 38 cases the erysipelas occurred accidentally in 23 cases, and was the result of inoculation in 15 cases; 17 cases were carcinoma, 17 cases were sarcoma, 4 either sarcoma or carcinoma.

The immediate and final results were as follows:

Of the 17 cases of carcinoma, 3 were permanently cured. In addition, 1 case of probable carcinoma (Hutchinson's) was well five years after the attack of erysipelas. Of the remaining 13, 10 showed improvement which, although temporary, undoubtedly added to the life of the patient in most cases. One case (Janike's) died, as a result of the erysipelas, on the fourth day.

As regards sarcoma, we find the curative action of the erysipelas even more marked. Of the 17 cases of sarcoma we find 7, or forty-one per cent., well and free from recurrence from one to seven years after the attack of erysipelas.

All of the cases except those of Dr. Coley were treated by injections of erysipelatous fluid. Dr. Coley used pure cultures of the streptococcus. Repeated injections were made, and it seems to be necessary to continue the inoculations in order to avoid recurrence. The theory that whatever good has resulted was due to the local reaction, is considered to be disproved by the fact that inoculations made at a distance from the tumor have been known to cause it to disappear (Spronck).

So far as the danger is concerned, it appears that among forty-four inoculations death occurred twice.

Dr. Coley states in a note that of late he has been using a preparation of the toxic principles of erysipelas in four cases of inoperable sarcoma. The injections have been made into the tumor itself, and repeated every forty-eight hours. The reaction has been almost identical in character with that produced by true erysipelas, though milder in degree, and it has always passed away within twenty-four to forty-eight hours. The temperature has never risen above 103½° F., and has usually dropped to normal the following day. He had also frequently made use of the toxic products of the bacillus prodigiosus in combination with the products of the erysipelas coccus, to intensify the action of the latter, and always with the desired effect. He concludes that, 1. The curative effect of erysipelas upon malignant tumors is an established fact. 2. The action upon sarcoma is more powerful than upon carcinoma in about the ratio of 3 to 1. 3. The treatment of inoperable malignant tumors by repeated inoculations of erysipelas is both practicable and not attended with great risk. 4. The curative action is systemic, and probably due chiefly to the toxic products of the streptococcus, which products may be isolated and used without producing erysipelas. 5. This method should not be employed indiscriminately until further experiments have proved its limitations.

Dr. Coley's paper will undoubtedly give a great impetus to the culture of streptococci, and we hope soon to see the question of their therapeutical value firmly settled.

ELECTRICAL EXECUTION AS A HIGH ART.

THE manner of the taking off of the convict Taylor at Auburn, on Friday, July 21st, adds another atrocity to electrical execution. Even in these days of newspaper sensationalism, the bristling superlatives of startling headlines are scarcely equal to the occasion. In fact, the horror of the thing staggers our faith in ordinary humanity, and stuns our appreciation of common decency. We are informed that after one thousand eight hundred and twenty volts were first switched into the body of the victim, his struggles were so violent that the death-chair was broken, and the partially bound body would have pitched forward, had not such an occurrence been prevented by the attendants. Then an attempt to renew the contact failed, and it was discovered that the armature had burned out. The sufferer was then taken from the chair and attempts made to kill him with morphine and chloroform. After an hour's dreadful and fruitless trial by these means, he was more regularly and judicially put to death by harnessing a borrowed electric light wire to the chair.

Of course, all these preliminaries required time, and demonstrated a fertility of resource and determination of purpose highly commendable in officers empowered to carry out the provisions of this new and most humane law.

It may possibly be claimed by the advocates of this improved thunderbolt method, that the victim was virtually killed by the first shock, just as was attempted in the case of Kemmler, who was likewise butchered at Auburn. Not even the ingeniously explanatory resources of the reflex phenomena can explain the necessity of chloroform and morphine for a full hour between shocks. And yet one of the medical witnesses dodges behind such an absurdity in the effort to prove that the execution was in the main a success. Another medical witness, in ignorant innocence of the business, almost verges on sarcasm by asserting that the breaking of the chair was considered a part of the judicial performance. Why the chair should have had three legs instead of four can possibly be explained on the score of economy to the State, certainly not on any other ground. What might have occurred in

case of a refusal of the electric light company to act, it is difficult to imagine. A very interesting legal question might obtain as to whether or not a victim could be judicially killed by chloroform or morphine when electricity was ordered. Happily, the arduous endeavors of the scientific experts to fulfil their repulsive mission left this question open for the possible repetition of a similar accident in a future case.

It is difficult to discover, in tendering the usual congratulations that obtain on similar occasions, who should be the proper recipients for them in the present instance. Perhaps the really deserving one should be the victim himself, who, after all the brutal bungling of that delectable band of operators, is now safely and surely dead.

MR. HART AND AMERICAN MEDICINE.

Mr. Ernest Hart has been among us bearing with him an observant eye and a receptive mind. He slipped through the East, and was made much of, as was proper, by our hospitable Western brethren. We should venture the suggestion that he had not seen quite all of American medicine, not having come in contact with the schools, hospitals, and medical men of Boston, Philadelphia, Baltimore, and New York, for there is something to be seen in these places. Yet he seems to have caught the spirit of the American situation very well, as will be seen by the extract from his letter published in another column. It is true that there is a certain lack of warmth between the active workers on our seaboard and those west of the Alleghanies. Many causes have contributed to this, but perhaps the most conspicuous was the strife stirred up by the question of the Code of Ethics. Yet the trouble was not, and is not, essentially connected with the Code, for Philadelphia and many other parts of the East warmly supported, the stand taken in behalf of this document. It was rather the gradual conviction that there was too much politics in the American Medical Association, and that busy and earnest men could not afford to waste time on personal issues, when their strongest ambition was to further medical science. It was with some such feeling that Philadelphia, a strong Code centre, became the leader in the movement to create a Congress of American physicians. We are glad to believe, however, that the medical profession of the country is becoming more and more harmonious, and already they show their willingness to work together on all important issues. We have faith in a great and united profession.

THE ARMY MEDICAL SERVICE.

We referred recently to the establishment, by an order of the Secretary of War, at the suggestion of Surgeon-General Sternberg, of an Army Medical School for the purpose of instructing approved candidates for admission to the Medical Corps of the Army in their duties as medical officers. The course of instruction in this school will be for four months, and will be given annually at the Army Medical Museum, in Washington, commencing on November 1st. The faculty will consist of four professors, and instruction will be given by them on the duties of medical officers in war and peace (including property responsibility, examination of recruits, certificates of disability, reports, rights and privileges, customs of service, etc.), on military surgery, military hygiene, and clinical and sanitary microscopy. After completing this course the medical officer will be assigned for some months as junior at a large military post, in order that he may become practically acquainted with the army regulations, the making of official reports, and other matters new to him, before he is thrown upon his own responsibility in some frontier post.

But even after this preliminary training the army medical officer cannot, or at least need not, vegetate, but every opportunity will be afforded him to keep abreast of the times in his professional acquirements. Books and instruments are liberally supplied, and he will also be given the chance to come in contact with the leading medical men in civil life, and to see what is actually being done by the most advanced workers in the large cities. Formerly it was the custom to assign for duty as attending surgeons in the larger cities the older officers, who might be regarded as entitled to a period of rest and a pleasant sojourn in social centres. But it is the intention of the Surgeon-General to utilize these assignments hereafter as a means of affording additional educational facilities to the medical officers, and to recommend to these posts surgeons who have not yet passed their examinations for promotion to a majority. These details will be made for one year only, instead of for several years as heretofore, in order that as many medical officers as possible may be enabled to avail themselves of the opportunities thus offered to become familiar with the practice of the leading physicians and surgeons in this country, and of attending medical lectures, meetings of medical societies, etc. At the end of this tour of duty medical officers will be required to make a detailed report to the Surgeon-General, showing how much of their time has been occupied by their official duties and to what extent they have availed themselves of the advantages offered for professional advancement.

All these changes are in the line of increasing to a marked degree the efficiency of the Medical Corps of the Army, and of rendering even more tempting than it has hitherto been an appointment to this corps. The position of an army surgeon is an honorable one; his life is not hard, as the lives of medical men are reckoned, his opportunities for study and for gaining distinction are great, he is provided for when sick and unable to work, and his pay is sure and increases steadily with his years of service.

There are at present five vacancies in the corps, and five more will occur within a year. First-class men are wanted to fill these vacancies, and it is evidently the intention of those in authority to make it worth while for such men to enter the service; and those who show a disposition to employ their leisure time in research work, relating to scientific medicine or hygiene, will receive due encouragement. As a further inducement to candidates, and to save them unnecessary expense, it has been decided that they may have a preliminary examination by a medical officer of the army stationed most conveniently for this purpose. This will enable those who would be rejected on account of physical defects, or whose preliminary education is unsatisfactory, to ascertain the fact without going to the expense of visiting a distant city for the examination, and will save them the humiliation of being known at home as rejected candidates. It will

also diminish the number of rejections by the Board. There has been a mistaken idea, due to the large number of rejections, that the examination is unreasonably severe; as a matter of fact, the examination is strict, but fair, and designed only to bring out as far as possible the practical knowledge of the candidate and to enable him to prove that he is a well-educated physician. The considerable number of rejections has been due to the fact that a large number of applicants have been men whose English education was defective, and who have appeared before the Board without having made any special preparation for the examination in professional branches.

The advantages of the service are undoubtedly very great for men who are willing to live under authority and to submit to the necessary discipline of military life. But the authority, while in a measure absolute, is seldom or never despotically exercised, and every regard is had, as far as may be compatible with the needs of the service, to the comfort and physical and mental well-being of the medical officer. There are few openings which offer greater opportunities to young men who have received a liberal medical education than does an appointment to the medical staff of the army under the present improved conditions of service.

News of the Week.

The Cartwright Prize of $500, established by the Alumni Association of the Medical Department of Columbia College (College of Physicians and Surgeons), New York, and open to universal competition, has been awarded to Dr. Ward A. Holden, of this city, for an essay entitled, "An Outline of the Embryology of the Eye."

A Lot of Bad Food.—The Board of Health of this city has, during the present year, destroyed 4,000,000 pounds of bad meat, fish, fruit, and vegetables. This shows what an enormous amount of putrefaction the human system craves and will in a measure withstand.

A Young Physician of this city seems to have a mania for getting inoculated. He went to Paris and was inoculated by Haffkine against the cholera. Recently he was inoculated, with much newspaper acclaim, with tubercle bacilli.

The International Medical Congress.—From Rome, under date the 17th ult., *The Lancet's* correspondent writes: "There can now be no doubt that in point of numbers alone, to say nothing of the importance of the monographs which were announced in my last communication as being expected from such *dii majorum gentium* of medicine as Virchow, Charcot, and Nothnagel, the coming Congress will be superior to the most frequented of its ten predecessors. In the first place, take Italy herself. There are about 20,000 possessors of medical diplomas in the peninsula, and of these it is safe to assume that no fewer than one-fourth will make an appearance at the Sections. To these 5,000 Italian medical men may safely be added the 3,000 practitioners and teachers of other nationalities who are already pledged to come, to say nothing of the fact that 'adesioni' to the number of 3,000 more are all but committed to be present. Allowing for abstentions and 'false starts' due to unforeseen causes, which affect no profession more than the medical, we may deduct 1,000 from the 11,000 thus compiled, and the balance of 10,000 'Congressisti' remains—a total exceeding by more than 4,000 the attendance at the Berlin Congress in 1890. It is, I find, from Germany that the majority of the foreign participants at the sittings will come. Certainly there is nothing of that international jealousy between Italy and the two other members of the Triple Alliance that caused the French representatives to be 'conspicuous by their absence' at the Berlin Congress. America also, both from her northern and southern divisions, will send many delegates—the physicians and surgeons of the United States especially."

A cable despatch from Rome, dated August 2d, reports that the Congress has been postponed until April next by reason of the prevalence of cholera.

Dr. Clark Gapen, of Chicago, has been appointed Medical Superintendent of the Illinois Insane Asylum at Kankakee, *vice* Dr. S. V. Clevenger, resigned. Dr. Clevenger was appointed a short time ago to succeed Dr. Dewey, who was removed for political reasons.

Opinions Concerning the Proposed National Bureau of Health.—Regarding this the *Weekly Medical Review* says: "The practical results so far obtained by prompt hygienic measures to prevent the spread of epidemics, as well as the advances made in the allied sciences, all point to the advisability of founding such a department, which would form the head or directing centre of all the State boards, and the results that could probably be obtained thereby would certainly be far-reaching and would contribute in no small degree to the perfection of civilization."

The Dietetic and Hygienic Gazette says: "A sanitary department would be the representative of the medical conscience of the nation; it would enlighten the people in all that relates to salubrity; as the head it would unite and profit by the labors of the State Sanitary Board, thus forming the centre or focus from whence the powerful action of the government would spread its benefits throughout the land."

On the other hand, the president of the New York City Board of Health and Dr. Cyrus Edson, Health Commissioner, have expressed their disapproval of the measure.

"Came Down To Be an American Doctor." — Dr. George Fischer, of Rochester, N. Y., a native of Germany, committed suicide on July 26th by taking chloral. Before taking the poison he made out his death certificate and left the following note:

"George A. Fischer, born at Hanover, Jan. 27, '48; graduated from Han Lyceum. Volunteered in '66 in Hanover Horse Guards; made officer June 27, after the battle of Sangensalka Served in the same capacity in 56 Westfalven, war of '70. Came to the United States in '73. Lost caste and came down to be an American doctor. Died according to certificate to be found in desk. With kind regards, Yankees,

"G. Fischer, No. 31 heaven, front parlor."

We do not find his name in the list of regular physicians of Rochester.

The State Board of Health.—The State Board of Health met at Albany, July 27th, and organized by the election of Dr. Florence O'Donohue, of Syracuse, as president. The Board expressed its appreciation of the work of the retiring president, the Hon. Thomas Newbold, of New York City, whose resignation as a member

of the Board has been in the hands of Governor Flower. The report of the secretary on his examination of the condensed milk factories at Brewster's, Putnam County, and at Purdy's Station, Westchester County, with reference to discharges therefrom into the east branch of the Croton River, recommends that the factories be not disturbed, providing proper steps are taken to treat the waste before it is discharged into the Croton water-supply. The report was adopted, and Secretary Balch will consult with Commissioner Dailey, of the New York Department of Public Works, with a view of remedying these dangers to public health.

Transplantation of Cancer-tissue.—Dr. Wenzel Kopfstein, of Prague, reports the successful implantation of cancerous tissue in the brain of a rabbit.

The Empress of Germany has written a testimonial in favor of a baby food.

Another Hospital for New York.—The erection of Grace Hospital will begin about October 1st. It will consist of a hospital proper and three supplementary buildings, called the House of Simeon, for old men; the House of Anna, for old women, and the House of the Holy Child, for children.

The Academy of Medicine for London.—A cable despatch to *The Sun* says: "A project is on foot for establishing a great academy of medicine in London by the amalgamation of the Royal College of Physicians, the Royal College of Surgeons, and other medical societies, but it is not probable that it will succeed. Each society suspects the others of the design to kill it, and so strong is the rivalry and jealousy among these grave and learned bodies that it has taken a month's cautious diplomacy to get together a small committee to consider the subject of the union."

The Progress of the Cholera.—Dr. W. A. Wheeler, chief of the Ellis Island medical staff, who returned recently from a three months' inspection of European ports, has sent the following letter to Immigration Commissioner Senner: "In reply to your letter of this date, asking my opinion as to the probability of an epidemic of cholera appearing in the ports whence immigration usually comes to us, I have to state that the outlook I consider to be most favorable at all except Mediterranean ports. At Hamburg, whence we get a large number of people, and which was, as you remember, visited by cholera last year, there has as yet been no recurrence of the disease, which it was greatly feared there would be. The city authorities have done and are still doing everything in their power to prevent its introduction from abroad, and to suppress it should it appear. At an enormous expense all water in the city now is filtered and purified. As the weeks roll by the chance of escaping the disease improves, so far as the northern ports are concerned. With regard to the Mediterranean ports, it may be said that sporadic cases of cholera appear in Marseilles and Naples almost every year, and the presence in those cities of a few cases does not by any means indicate that an epidemic will follow. Since the last epidemic at Naples the sanitary condition of the city has been greatly improved. First, by the introduction of water from a mountain lake situated fifty miles in the interior, the water being of great purity and brought underground to Naples. An active municipality is also alive to the dangers to the commerce of Naples in the event of an epidemic of cholera, and will use every effort to suppress the disease should it appear. You will therefore see that I am inclined to be very hopeful regarding any serious outbreak of cholera in foreign ports this season, and do not anticipate any marked diminution of immigration from that cause."

Unfortunately, the latest reports are not of such a nature as to justify fully Dr. Wheeler's hopeful view. The outbreak of the disease at Naples is much more serious than the authorities in that city have tried to make it appear. The Government suppresses telegrams concerning the epidemic, and the newspapers make no mention of the prevalence of the disease in the city. Nevertheless, a despatch from London, dated July 31st, says that "from July 20th to July 28th there were 292 cholera cases registered in Naples, and 157 deaths. The daily average was 37 cases and 17 deaths. On July 22d, 45 fresh cases and 24 deaths were reported. The number of cases and deaths has declined since then." In Russia also the cholera is by no means extinct. Official returns made at the end of July show a marked increase of the disease in various parts of the empire. The figures show that from July 9th to July 22d there were in the Government of Podolia 1,165 cases and 350 deaths, as against 499 cases and 122 deaths during the week preceding. In the Government of Orel, from July 16th to July 22d, there were 234 cases and 91 deaths, as against 148 cases and 52 deaths during the previous week. In the Government of Toola there were 77 cases and 19 deaths from July 16th to July 22d. In the preceding week there were only 31 cases and 8 deaths. In Moscow, from July 16th to July 22d, there were 72 cases and 21 deaths. The epidemic exists, though in less severe form, in the Governments of Viatka, Kazan, Riazan, Oofa, and Simbeersk. The State Department at Washington has received a cable despatch from the United States Consul at Smyrna, stating that cholera exists in that port. The outbreak of the disease in this important centre of Mediterranean trade is regarded as of much significance. Smyrna is a port of Asiatic Turkey. Its trade is principally with places on the Mediterranean. The condition of affairs in the province of Corunna, Spain, where a number of cases of suspicious sickness were reported, is serious. It has transpired that forty persons have been attacked with a choleraic disease within the last few days. Of the persons attacked twelve have died. It is believed that the disease is Asiatic cholera, although there is no official notification to that effect. Cholera prevails also at Alessandria, in Italy. One case was reported in Hamburg on July 27th. The patient was a workingman, who was seized with cholera in the street, and was removed to the hospital.

The Water-supply not Appreciated.—In the slums of Chicago there are sixteen thousand residents and only four bath-tubs, two of which are disconnected.

Mississippi Valley Medical Association.—The nineteenth annual meeting of the Mississippi Valley Medical Association will take place in Indianapolis, Wednesday, Thursday, and Friday, October 4, 5, and 6, 1893. A general session will be held each morning, and the afternoons will be devoted to section work. There will be three Sections at this meeting, viz.: one on General

Medicine, one on General Surgery, and one on Obstetrics and Gynecology, the last mentioned having been added since the last meeting. Frederick C. Woodburn, No. 399 College Avenue, Indianapolis, is secretary.

Died at the Age of One Hundred and Thirty Years.—Peter Arreola, who recently died aged one hundred and thirty, at Tarimore, Mexico, was probably the oldest man in North America. He left 220 living descendants, many of whom are prominent in Mexican affairs.—*St. Louis Courier of Medicine.*

Stoechiology.—There are a great many ways of curing consumption, but the "Stoechiological Method" has the advantage in respect to its nomenclature, at least. So far as we can find, all there is to stoechiology is hypophosphites, a class of drugs which some people think do good in some inscrutable way.

Professor Christian Fenger, formerly professor of surgery at the College of Physicians and Surgeons, has been elected to, and has accepted, a chair of surgery and clinical surgery at the Northwestern University Medical School.

The Kansas Way.—The following appears at the foot of a bill-head of a Kansas physician. It is unique, original, and pointed, and we presume effective: "A prompt settlement of this bill is requested. If bills are paid monthly, a discount of ten per cent. is given. Bills not paid promptly will be passed to my attorney for collection. If you pay your physician promptly he will attend you promptly, night or day, rain or shine, while your slow neighbor suffers and waits, as he made the doctor wait, and while he is waiting the angels gather him in." —*Kansas Medical Journal.*

A Doctor in Pine Bluff, Ark., who is hardly twenty-one years of age, has done eleven laparotomies, all successful. This proves that the doctor is a very enterprising man; but what can be the matter with the Pine Bluff ovary?

Dr. S. C. Ayres has been appointed Professor of Ophthalmology, and Dr. J. C. Culbertson Professor of the Principles and Practice of Medicine, in the Cincinnati College of Medicine and Surgery.

The First Symphyseotomy on the Pacific coast was recently performed, successfully, by Dr. H. R. Holmes, of Portland, Ore. Up to June 5th, this operation had been done twenty times in the United States, and twice in Canada.

Fracture of the Cervical Spine.—There is at present in the Harlem Hospital a young man, twenty-two years of age, who is living with a broken neck, and whose prospects for continuing to live are excellent. He was struck by the arm of a windlass, the blow rendering him insensible for a time, and an examination proved that there was a fracture of the fifth cervical vertebræ. Just now the head is supported by a plaster-of-Paris dressing, but before leaving the hospital he will be provided with a permanent apparatus for the purpose. There is a second case of broken neck in this city, at one of the Dime Museums. The patient is making a quiet and comfortable living by simply exhibiting his splint and dropping his head on his trunk six times a day. With this man the broken neck solves a very important economic problem.

A Bequest to a Philadelphia Hospital.—The German Hospital of Philadelphia receives a gift of one hundred thousand dollars by the will of the late A. J. Drexel.

Some of our Philadelphia exchanges have adopted the practice of leaving off the terminal syllable "al" in words like physiological, biological, pathological, etc. The reader, before he gets through an article thus scientifically abbreviated, feels as though he had the hiccough, or, as one might say, very singultic.

Carbonated Waters.—A great many people drink carbonated waters and believe that they thereby both serve their health and please their palate. It will be a shock to them to learn that microbes can live with CO_2, and that saprophytes have been found in water of world-wide reputation for its sparkling character. Not that any very serious-minded or specifically malignant organisms exist in these pleasantly potable media, but still carbonated waters may contain microbes.

Acute Rheumatic Arthritis. — Dr. Sahli, in the *Deutsches Archiv für Innere Medicin* for July, discusses this disease in an interesting paper. He considers that it is probably an infectious disease, and in this connection he remarks upon its acute febrile course and the difficulty of diagnosis between it and septic or pyæmic affections of the joints or even osteo-myelitis, and also comments on the frequent detection of staphylococcus in the vegetations in cases of post-rheumatic endocarditis (Birch-Hirschfeld, Mantel, and others). He then describes a case of rheumatic fever in a girl of sixteen, being the second attack, which ended fatally, and how after death a yellow staphylococcus was found in the endocardial excrescences, synovial membrane, pericardium, pleura, swollen bronchial glands, and in the blood of the left ventricle. Dr. Sahli has in several other cases cultivated a similar staphylococcus from fluid taken during life from inflamed joints and also from the blood of rheumatic patients.—*Lancet.*

Secret Remedies for Diphtheria.—Dr. Aronson's refusal to communicate the method of preparing the extract from serum by which he hopes to be able to cure diphtheria was the occasion of some discussion at the meeting of the Berliner Medicinische Gesellschaft on June 14th. The Society did not enter upon any consideration of the merits of the preparation, and the President, Professor Virchow, repeated his previous declaration that, had he been aware of the object of the paper, he would not have allowed it to be read.—*Lancet.*

A Novel Mode of Electrical Treatment.—M. d'Arsonval has proposed to the Académie des Sciences a new plan of treating patients by electricity. The subject is enclosed in a large coil of wire through which alternating currents are passed, and the patient's body thus becomes the seat of alternating induced currents which correspond in frequency with those which circulate in the coil. When rapidly alternating disruptive discharges are passed through the coil, it is possible to demonstrate the presence of the induced currents in the patient by placing an incandescent lamp in circuit between his hands, as it is brought to incandescence, though the patient feels nothing. The influence of the treatment upon the processes of nutrition are considerable, the absorption of oxygen and the elimination of carbonic acid gas being largely increased.

Reviews and Notices of Books.

Créosote et Tuberculose; Revue Générale; Traitement de la Tuberculose Pulmonaire par la Créosote administrée par Voie Rectale. Par le Dr. Henri Audeond, Médecin Diplômé de la Confédération Suisse; Ancien Assistant d'Anatomie Normale; Ancien Médecin-Assistant au Dispensaire des Enfants Malades; Assistant à la Clinique Médicale de l'Université; Médecin Interne à l'Hôpital Cantonal. Genève: J Studer. 1893.

This is a very carefully prepared review of the question of the employment of creosote in the treatment of tuberculosis, and especially of the method of administrating the drug by the rectum. The first part is devoted to a general review of the varying fortunes of creosote in this respect during the past sixty years, including also a chapter on the use of guaiacol. In the second part the writer treats at some length of the rectal administration of the remedy in pulmonary tuberculosis. The conclusions of the author are that creosote is a valuable remedy in the treatment of tuberculosis although it is not a specific, and that the rectal method is the preferable way of administration. There is a valuable and quite complete biographical list of journal articles bearing upon the subject.

Traitement Chirurgical des Affections Inflammatoires et Néoplastiques de l'Uterus et de ses Annexes. Par E. Doyen (de Reims), Professeur Suppléant à l'École de Médecine; Chirurgien Suppléant des Hôpitaux. Paris: Bureaux des Archives Provinciales de Chirurgie. 1893.

This is an exhaustive review of the treatment of inflammatory diseases of the uterus and its adnexa, based upon the statistics of three hundred and twenty-four operations. The author also describes two hitherto unpublished methods of abdominal and vaginal hysterectomy devised by himself. The work is illustrated by forty-seven woodcuts.

System of Diseases of the Ear, Nose, and Throat. In two Volumes. Edited by Charles H. Burnett, A.M., M.D., Emeritus Professor of Otology in the Philadelphia Polyclinic, etc. Philadelphia: J. B. Lippincott Co. 1893.

Volume I. treats of diseases of the ear, nose, and naso-pharynx. It consists of 789 pages, printed in good-sized, legible type, on paper that is not trying to the eye, and is well-bound in a volume of convenient size. The pages are embellished by numerous illustrations, consisting of twenty-four plates and two hundred and thirty-six cuts, distributed throughout the volume in a manner to more clearly elucidate the text. The avowed purpose of the publication is "to place before the profession a practical work on the diagnosis and treatment of diseases of the ear, nose, and naso-pharynx," and "the authors have aimed to give practical conclusions arrived at by other investigators and by themselves rather than to discuss theories." There are twenty-three exhaustive articles in volume I., contributed by as many authors. These, beginning with the articles on anatomy, are arranged in logical sequence, in a manner to form a complete systematic treatise. The subject-matter is divided into two parts: Part I. treats of the ear; Part II., of the nose and naso-pharynx. Among those who have contributed to this volume we find the names of Drs. Edward B. Dench, New York; Robert Barclay, St. Louis; Gorham Bacon, New York; Charles H. Burnett, Philadelphia; Clarence J. Blake, Boston; Charles A. Oliver, Philadelphia; Clinton Wagner, New York; Francke H. Bosworth, New York; Carl Seiler, Philadelphia; George W. Major, Montreal, Canada. These names are sufficient guarantee of the excellence of the articles.

The plan pursued by the editor for the construction of the "System" has much to commend it. It embodies the work of specialists in the particular branch of their specialty, to which they have given the greatest attention, as a rule, and must necessarily be of greater excellency than it could be had it been the work of one author. The work is essentially one for the profession. For the practitioner, general or special, it is a valuable addition to the literature on the subjects treated of. The publication, certainly, abundantly fulfils the avowed purpose of its projector.

Manual of Chemistry. A Guide to Lectures and Laboratory Work for Beginners in Chemistry. A Text-book Specially Adapted for Students of Medicine and Pharmacy. By W. Simon, Ph.D., M.D., Professor of Chemistry and Toxicology in the College of Physicians and Surgeons; Professor of Chemistry and Analytical Chemistry in the Maryland College of Pharmacy, Baltimore, Md. Fourth Edition. Philadelphia: Lee Brothers & Co. 1893.

It is an evidence of the appreciation with which this excellent work has been received that it has already run through three editions, the third having been exhausted within a year. In preparing this fourth edition, Professor Simon says that he has improved the opportunity afforded him for a thorough revision of the matter contained in it, and has brought the work up to date by incorporating in it all the additions made necessary by recent advances in chemical science. The work is divided into seven parts, the first treating of the fundamental properties of matter, the second of the principles of chemistry, and the third and fourth of the non-metallic and metallic elements and their compounds. The fifth part deals with analytical chemistry and contains full directions for the student engaged in laboratory work. In the sixth part the difficult subject of the carbon compounds is put before the reader in a remarkably clear and comprehensible form, and the concluding chapter is devoted to a consideration of physiological chemistry. The book is illustrated by woodcuts and by seven colored plates, representing a large number of chemical reactions.

On the Chemistry and Therapeutics of Uric Acid, Gravel, and Gout. Being the Croonian Lectures for 1892. Delivered before the Royal College of Physicians of London. With Additions. By Sir William Roberts, M.D., F.R.S. London: Smith, Elder & Co. 1892.

This handy little book of some one hundred and thirty pages contains much more that is of solid practical worth than many a bulky volume three and four times its size. It is the work of a master-hand who is thoroughly acquainted with his subject and who possesses the happy faculty, none too common, of being able to impart his knowledge to his readers. No one can rise from a careful reading of these lectures without feeling that he has acquired clearer perceptions of the complex subject of the chemistry of uric acid and the urates, and has learned some facts that will be of practical utility to him in his management of these trying cases of gout and gravel. The four lectures deal respectively with the chemistry of uric acid and the urates and the comparative physiology of uric acid, with the chemistry and prophylatic treatment of uric-acid gravel, with the chemistry of uratic precipitation in gout, and with the bearings of this on the therapeutics of gout. The index is rather brief, but in a work of this nature, which should be read through and studied from cover to cover, a very complete index is perhaps not necessary.

Some Facts About Iron in Chlorosis.—Dr. Ralph Stockman, as a result of a number of experiments, concludes that organic iron compounds are not nearly so good as inorganic. He got poor results from Kobert's hæmol and hæmogallol; he found that manganese was of no use, nor was hydrochloric acid.

Society Reports.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-ninth Annual Meeting, held July 19th and 20th, at Fort Griswold House, New London, Conn.

FIRST DAY, WEDNESDAY, JULY 19TH—MORNING SESSION.

THE Society was called to order by the Vice-President, Dr. George C. Harlan, of Philadelphia.

The Relation of the Patellar Tendon Reflex to some of the Ocular Reflexes found in General Paralysis of the Insane.—A paper with this title was read by DR. CHARLES A. OLIVER, of Philadelphia.

The following propositions were offered:

1. In some of the cases in the second stage of the disease, especially where the patellar tendon reflexes were unequally exaggerated, there appeared to be an irregular and unequal spastic enervation of the two irides, causing irregularities in pin-point pupil forms.

2. In a few cases, especially in the third stage of the disorder, where the patellar tendon reflexes were unequally diminished, the pupil-size, though small, and its shape, though somewhat irregular, seemed to be but little acted upon by any powerful mydriatic.

3. In many cases, especially in comparatively young subjects, in the third stage of the disease, where the patellar-tendon reflexes were unequally diminished, there appeared to be an unequal paralytic enervation of the two irides; the pupillary dilatation manifesting itself at times, though not as a rule, in the eye with the greater amount of objective optic-head degeneration and retinal change.

4. In a few cases, especially in men beyond middle life, in the third stage of the disorder, where the patellar reflexes were markedly diminished and where the ataxias were quite pronounced, there were marked temporary asymmetries of pupillary form, one often being quite small and irregular for several examinations, while its fellow was large and ovoid, or oval.

5. In quite a number of cases, especially in the advanced stages of the disease (although seen in a number of cases in their earliest stages), where the patellar-tendon reflexes were unequally exaggerated or diminished, there was a failure of the irides to respond to even major degrees of light stimulus; this being true not only for those subjects exhibiting a true spastic myosis, but more especially shown in those instances where, with partial dilatation of the pupil, mydriatics failed to act.

6. In many instances, especially in the older cases, where the patellar-tendon reflexes were, as a rule, unequally diminished, or even lost, there was not only failure of iris response to the strongest light stimulus carefully thrown upon the retina, but where obtainable the irides seemed to fail to react to the various coarse and rough subjective and objective procedures necessary to be used in order to evolve both separated and associated efforts for accommodation and associated efforts for convergence.

7. In some instances, where ciliary muscle innervation could be satisfactorily obtained, both the spastic excitation and the paralytic enervation, at times found by subjective reading tests and objective study with the retinoscope, seemed to be in direct ratio with the patellar-tendon reflexes as the iridic changes.

8. In quite a number of cases where there was marked inequality of the pupils, with more or less want of reaction of the irides to light stimulus, the patellar-tendon reflex on the side of the larger pupil seemed to be the one the more greatly diminished.

9. In a number of instances, especially during the very earliest stages of the disease, where the patellar-tendon reflexes were beginning to lessen to unequal degrees, there often appeared momentary secondary ataxic dilatation of the pupil during exposure to strong light stimulation.

10. In many cases, especially during the second stage of the disorder, when the patellar-tendon reflexes began to become irregular and inconstant, pupillary inequalities, as expressive of unequal iris innervation and action, became more and more constant.

Clinical History of a Case of Spindle-celled Sarcoma of the Choroid, with a Study of the Microscopic Condition of the Growth.—DR. OLIVER, also reported the following case:

The patient, a man thirty-four years of age, consulted the writer on account of trouble with the left eye. Five years previously he suddenly noticed that objects situated to the right became dimmed when he attempted to look at them with the left eye. This gradually and painlessly extended over the whole field of vision, until in a little more than three years' time, the eye became blind.

In June, 1890, the tumor of the choroid was discovered by Dr. J. H. Thompson, of Kansas City. There was a history of syphilis, but treatment had no effect upon the growth, and a diagnosis of sarcoma was made and operation urged, but not accepted.

When seen by the writer, in June, 1892, a large vascular growth was seen in the upper part of the globe. Immediate enucleation was advised and accepted. The operation was done the following day. The patient has recently been seen and is perfectly well, with no evidence of return.

Microscopical examination showed the growth to be a spindle-celled sarcoma. Sections and photographs were presented.

Sarcoma of the Choroid.—DR. EMIL GRUENING, of New York, reported the case of a patient, a woman, aged thirty, who was seen April 17th, on account of diminution of sight in the right eye. The ophthalmoscope showed the retina in the macular region pushed forward. This projection was about four discs in diameter. This had given rise to no symptoms with the exception of a scotoma. Sarcoma was diagnosed and the eye was removed. Examination showed the growth to be a spindle-celled sarcoma.

Sarcoma of the Eyelid.—Dr. Gruening then read a report of a case of this affection which he said was exceedingly rare, the case reported being the only one seen by the author. The patient was a young man twenty-three years of age. He came under observation January 1, 1893. Five years previously he had noticed a small swelling on the lower lid of right eye. This bled freely and irregularly: it was operated on in another city, but soon recurred. When seen it was as large as a hazel-nut, and involved two-thirds of the lid, with a nodular mass on the inner surface of the lid which readily bled. The skin covering the mass was freely movable. A small portion of the growth was removed and found to be sarcomatous. The tumor, with the entire thickness of the lid, was then removed and the lid restored by a plastic operation.

DR. H. KNAPP, in the discussion, reported two cases of traumatic sarcoma of the lid, both terminating fatally.

Tumor of the Iris, Probably Tubercular. — DR. GEORGE C. HARLAN, of Philadelphia, related the case of a male child, who was born September 5, 1890. On February, 1893, weakness of the right eye, with photophobia and lachrymation, was noticed. The child was first seen March 6, 1893. There was some conjunctivitis but no chemosis. There was a small posterior synechia. A number of small, yellowish-white, rounded nodules were noticed on the periphery of the iris. These increased rapidly in size and others were added. The deposit increased rapidly and soon filled the upper outer third of the anterior chamber and completely covered the pupil. Intense photophobia of the sound eye developed, and enucleation of the diseased eye was done March 15th. After the operation the condition of the child rapidly improved. Microscopical examination indicated that the lesion was probably tubercular, although bacteriological examinations gave negative results.

Reflections upon a Disastrous Case of Ophthalmia Neonatorum was the title of a paper by DR. B. ALEX-

ander Randall, of Philadelphia. He referred to the great importance of strong, clear-cut expressions in relation to preventable disease, in order that the community and the profession may be properly aroused to the dangers of the situation and spurred to thorough and persistent efforts to combat them. Yet such expressions have danger to those using them, and to others, since careful precautions may fail to prevent the disease or bring it to a successful termination. This point was brought painfully home to him by a disastrous case of ophthalmia neonatorum in which he could find no fault with the prophylactic or the therapeutic measures, yet both eyes were lost. Some authoritative statements as to the preventability and curability of the disease were repeatedly called to the attention of himself and the accoucheur. He wished to protest against too uncompromising claims as to the powers of medical measures, since such may be two-edged weapons which turn most seriously against their authors or other medical men who have really done all that human means could effect.

Clinical Notes on Some Refractive and Muscular Cases.—Dr. B. L. Milliken, of Cleveland, O., said that in very high degrees of astigmatism the use of the ophthalmoscope was the most satisfactory method of testing refraction. Six cases were cited where attempts were made to correct by the ordinary means of testing, with no satisfactory results, while the ophthalmoscope gave most excellent corrections. In one case a lad, aged thirteen, with history of fronto-temporal headache for years, had a high degree of mixed astigmatism in the left eye, which under a mydriatic gave no satisfactory results, but with the ophthalmoscope the following was obtained, the right eye having only a moderate degree of astigmatism:

O.S. + 4 D. cyl. ax. 20° ⊂ 4 D. cyl. ax. 110° V. = $\frac{6}{9}$.

This glass, with the proper one for the right eye, gave great relief and has been worn with comfort.

In another case, that of a man, aged thirty-nine, there was high mixed astigmatism in both eyes, and especially marked in the right eye, which with a mydriatic had to be worked out with the ophthalmoscope and gave the following:

O. D. — 10 D. cyl. ax. 90° ⊃ + 7 D. cyl. ax. 180° V. = $\frac{6}{9}$.
O. S. — 6 D. cyl. ax. 100° ⊃ + 4 D. cyl. ax. 10° V. = $\frac{6}{9}$.

These glasses have been worn constantly for two years with the greatest comfort, the man working all day at bookkeeping. The ophthalmometer showed great irregularity in the images, and could not be used with any accuracy in testing the refraction.

Several cases were reported showing what could be done with prisms in correcting muscular insufficiencies, and the question was brought out as to the advisability of wearing prisms at various angles, for the purpose of correcting both a lateral and a vertical muscular insufficiency with the same glass; for instance, in a case of a lateral insufficiency of say 1°, and a vertical insufficiency of 1°, instead of making two prisms to correct—one at 90° and the other at 180°—place a 2° prism at 45° or 135°, right or left, as the case might be. The histories of several cases of this kind were given in which patients had worn the glasses thus with much benefit, and a trial of this kind was urged.

Several Cases in which the Vertical Diplopia Test Proved Untrustworthy.—Dr. Samuel Theobald, of Baltimore, described four cases in which the cover test showed a high grade of exophoria, both in distant and near vision, but in which the vertical diplopia test failed entirely to demonstrate the presence of the condition, in some of the cases even indicating esophoria. In one of these cases, and also in a case of esophoria, the notes of which were given, it was found that when, during the application of the vertical diplopia test, the cover test also was employed, a squint would show itself in the excluded eye, which the vertical prism failed to bring out, and which would disappear upon the removal of the cover, though the vertical diplopia was still maintained, showing that the latter had no controlling influence over the action of the lateral muscles. The cases, such as described, in which the vertical diplopia test proved untrustworthy are, however, comparatively rare and the writer still employs it daily and considers it of the greatest value.

Useful Vision Maintained by Means of a Totally Dislocated Lens.—Dr. Theobald, of Baltimore, presented an additional note on this case, which had previously been reported to the Society. The feature of interest was that a fragment of the dislocated lens, the capsule of which had ruptured two years before, fell through the pupil into the anterior chamber, where it remained for six months, resisting the solvent and opacifying action of the fluids of the eye so completely as to retain its transparence and its sharply cut angles. It closely resembled a bit of yellowish glass, and might easily have been mistaken for a foreign body. As its presence in the anterior chamber began to cause considerable irritation, the pupil was dilated, and it was caused to fall again into the vitreous chamber, its return to the anterior chamber being prevented by the application of a myotic. This was followed by the disappearance of the irritation, which has not since returned. The insolubility of the lens fragment is the more remarkable in view of the fact that the patient was but twenty-two years of age at the time the lens capsule ruptured.

A Series of Wools for the Ready Detection of Color-blindness.—Dr. Charles A. Oliver, of Philadelphia, had made the following modifications in the Holmgren series: Five individual tests are employed—pure green, pure red, rose, pure blue, and pure yellow. Loose and separate skeins of wool were employed. The colors were made of equal relative intensity. The value of the color used in each test-skein was expressed. The set was so constructed that it could be used by any intelligent layman. The test was so constructed that passing color-changes could be preserved and permanently kept for future comparison. The test was so constructed that written and verbal expressions of the character and the amount of the subnormal color perception could be given. The wools were made of one grade of manufacture and dyed with vegetable material.

After several years' trial the writer found that he could dispense with all but the five principal test-skeins, five pure match skeins, and eighteen confusion-skeins of relative equal value to the pure match-skeins.

Afternoon Session.

Gouty Retinitis, Choro-retinitis, and Neuro-retinitis.—Dr. Charles Stedman Bull, of New York, presented a communication with this title. The paper was based upon a study of the retinal changes found in over one hundred gouty patients. Five of these cases (two with autopsy) were reported in detail.

The points to which attention was drawn were:

1. The changes in the fundus are always bilateral though rarely symmetrical in the two eyes.

2. The degeneration in the walls of the blood-vessels and in the retina cause marked impairment of central vision, little or no impairment of peripheral vision, and never end in blindness.

3. The loss of central vision is always progressive up to a certain point, unless the cause of the disease is recognized early in the outset and immediately and properly handled. Improvement of the vision after the disease is established cannot be expected.

4. Hemorrhages into the retina are rare except in the beginning of the disease. Their absence later is probably due to the fact that the strength of the vascular wall is increased by the deposit, though its elasticity is diminished.

5. The most marked feature in the fundus is the development of the arterio-sclerosis and phlebo-sclerosis. This is seen by the ophthalmoscope in the vessels of the retina, and the microscope shows that the degeneration

exists as well in the vessels of the choroid and optic nerve.

6. Another almost equally pathognomonic symptom is the peculiar yellowish granular exudation in the retina, located by the ophthalmoscope around the posterior pole of the eye, and generally leaving the macula intact, and proved by the microscope to be mainly in the nerve fibre layer, though found in all the layers except that of the rods and cones.

7. The changes in the optic nerve-fibres seem to be almost entirely intraocular, and cannot be traced for any great distance back of the eyeball.

Retinitis Punctata Albescens.—Dr. Myles Standish, of Boston, said that these cases are not uncommon, yet the literature of the subject is surprisingly small for a condition which presents such a striking picture to the ophthalmoscope. The majority of cases come on account of some discomfort in the use of the eyes, and the white, rounded, glistening spots are discovered in the retina in the course of the examination. After a time comfort in the use of the eye returns, but without the spots disappearing. What the substance is that produces the appearance is undetermined. A case was reported which was of special interest, as it apparently filled out the clinical history of these cases in the prodromal and acute stages.

Removal of Hard Cataract by Suction.—Dr. Lucien Howe, of Buffalo, said it was probable that every operator has occasionally experienced difficulty in completing the final act of extracting the lens. In order to obviate this difficulty the writer had employed an instrument similar to a large dropping-tube, by means of which a partial vacuum could be made. The tube was applied to the protruding lens, enabling the operator to draw it out.

Dr. Frank W. Ring, of New York, exhibited an ocular mask of papier-maché, to be used for the protection of the eye after cataract operations.

The Artificial Ripening of Cataract.—Dr. Edward Jackson, of Philadelphia, reported a series of cases which had been treated by tapping the anterior chamber, drawing off the aqueous humor, and massage of the lens through the cornea, as suggested by Pooley and advocated by White.

The operation was followed by very little reaction; there being no iritis or posterior synechia in any case. In patients over fifty years of age the operation was followed by rapid increase in the opacity of the lens and early maturity of the cataract. In patients under thirty-five years of age no effect upon the existing lens opacity was produced.

The author concluded that this method of ripening cataract was certainly more efficient than that of Forrester—iridectomy and massage; was almost entirely free from danger, and was probably a better means of avoiding prolonged practical blindness than the extraction of the immature cataract.

Traumatic Dislocation of the Iris under the Unbroken Conjunctiva—The Eye Damaged but Preserved—Typical Sympathetic Ophthalmia in the other Eye.—Dr. Herman Knapp, of New York, reported the following case:

Mr. M——, aged forty-five, came under observation December 21, 1892. Ten days before his left eye had been struck with the head of a small pet dog with which he was playing. The eye had been red and black ever since, but not painful, the sight impaired. On the inner side of the cornea, and 2 mm. from its margin, the conjunctiva was raised by a black mass which proved to be the iris. The conjunctiva showed no wound or scar. The whole iris was found absent from its normal position. The lens was in place and transparent. There was no neuro-retinitis or isolated rupture of the choroid. Vision equals $\frac{15}{200}$. The right eye was free from any irritation. The patient was directed to bandage the injured eye lightly, and not use the other eye and keep quiet. Everything did well until twenty-nine days after the accident when symptoms of sympathetic inflammation appeared in the right eye. Under active treatment the attack subsided, but relapses occurred and vision in the right eye was completely lost. In the left eye vision equals $\frac{20}{70}$, and the displaced iris has shrunken to a flat, blackish mass scarcely raised above the conjunctiva.

Second Day, Thursday, July 20th—Morning Session.

Removal of Steel from the Vitreous with the Electromagnet.—Dr. E. E. Holt, of Portland, Me., had previously reported six cases treated by this method. In the present paper he reports three cases. In all the pieces of steel had entered through the anterior chamber, fracturing the lens. The conjunctiva was separated and an incision made through the sclerotic, back of the equator of the eye, the knife in each instance striking the foreign body. The electro-magnet was then introduced and the steel removed. The lens was subsequently absorbed and good vision obtained in every case, notwithstanding the fact that in the third case there was pus in the anterior chamber when the case came under observation.

A Permanent Magnet for Use in Removing Foreign Bodies from the Cornea was described by Dr. Walter B. Johnson, of Paterson, N. J. It consists of a bar of steel, cone-pointed and elongated at each end. It is charged by rotating it within the magnetic field of a generator. It will continue in full magnetic strength for a long time. It has served an excellent purpose on several occasions in removing small particles of steel from the cornea, which had perforated and almost entered the anterior chamber.

Suppression of the Visual Image.—Dr. Walter B. Johnson, of Paterson, N. J., read a paper on this subject. In convergent strabismus there is present an amblyopic condition affecting the squinting eye. Hypermetropia was considered by Donders and others as the most frequent cause of convergent squint, exciting excessive efforts at accommodation, resulting in convergence, confusion of images, and subsequent mental suppression of visual image in one eye, finally terminating in an amblyopic condition. It has been claimed by Schweigger, Alfred, Graefe, and others that amblyopia is not caused by squint but exists as a primary or congenital condition. This produces convergence in consequence of confusion of images. The variety of amblyopia in question is apparently a purely physiological condition, the fundus being normal. The amblyopia is sometimes overcome by correction of the visual defects, but vision in the amblyopic eye rarely becomes equal to that of the fellow-eye.

The following case was reported: T. K——, aged nineteen, had been cross-eyed since the age of three years. He has never been able to discern any object with left eye. There was hypermetropia in right eye. Vision in left eye equalled fingers at six inches. On June 13th enucleation of the right eye was required as the result of accident. June 18th, vision in left eye had increased to fingers at three feet. Examination showed a hypermetropia of 1.50 D. Under careful practice the vision in left eye rapidly improved, so that by July 1st he could read $\frac{20}{15}$ with correcting glass, and Jaeger, No. 1, at twelve inches. Examination three years after the loss of the eye showed that the improvement had continued.

In this case, whatever was the change which led to the loss of vision, it was not structural either in the eyeball or the nerve centres, but was in all probability a pure amblyopia which resulted from the long-continued mental visual suppression.

A Case of Congenital Cyst of the Orbit, with Anophthalmus, was reported by Dr. George C. Harlan, of Philadelphia. The patient was a well developed and healthy child, five months old. The left eye and appendages were perfectly normal. A tumor about the size of a small hen's egg filled the right orbit and projected considerably beyond it. The orbit was fully of

adult size, and the lids distended to more than twice their normal size. The skin was movable and of natural appearance. The cilia were well developed. The lids were separated about two centimetres, the exposed conjunctiva was congested but not much changed. There was no discharge. There was nothing to mark the position of the cornea. There was no movement in the tumor, no pulsation, and it was incompressible. Fluctuation was decided, but very tense.

As the tumor was growing and the deformity great, it was decided to remove it. Incision through the conjunctiva gave exit to a quantity of clear watery fluid. The cyst was simple, the outer portion being fibrous and tough, and the inner delicate, semitransparent, and bluish.

The child died twenty-four hours after operation, apparently from exhaustion following upon shock.

A careful inspection of the orbit was made after death. There was no connection with the intracranial cavity. There was no indication of any aperture. Nothing resembling an eye could be found in the extirpated cyst, though at the bottom of the sac there was an undefined mass of tissue.

A review of the literature was given, and the author concluded that the tumor was probably formed of the embryonic tissues of the eye, and that it was either an exaggerated hydrophthalamus or a fœtal encysted coloboma which, by its early inception and enormous growth, had prevented the evolution of the eye.

Restoration of the Upper Eyelid by means of a Flap Taken from the Cheek.—Dr. Samuel B. St. John, Hartford, Conn., demonstrated a method which was applicable to cases in which the upper lid had been destroyed by disease or injury, or in which the lid was removed by operation. In making the flap the incision commences about half an inch in front of the ear, and runs forward below the lower lid about half an inch, and continues until the side of the nose is reached. It is then carried downward and until the flap is of sufficient width, and then taken backward. The flap is next separated and secured by numerous stitches to the freshened surface above. The gap left is closed by separating the tissues of the cheek below the wound and sliding them upward.

Two cases were reported in which this plan had been used with success, and photographs of the patients were shown.

Executive Session.—The following were elected to membership: Dr. F. E. Cheney, of Boston, Mass.; Dr. Charles H. Thomas, of Philadelphia, Pa.; Dr. William H. Wilmer, Washington, D. C.; Dr. H. B. Chandler, Boston, Mass.; Dr. J. E. Weeks, New York; Dr. George Fiske, Chicago, Ill.; Dr. Edward Fridenberg, New York; Dr. William Cheatham, Louisville, Ky.

Officers for Ensuing Year.—*President*—Dr. George C. Harlan, of Philadelphia, Pa; *Vice-President*—Dr. O. F. Wadsworth, Boston, Mass.; *Secretary* and *Treasurer*—Dr. Samuel B. St. John, Hartford, Conn.; *Corresponding Secretary*—Dr. J. S. Prowt, Brooklyn, N. Y.

The Society adopted a by-law limiting the membership to one hundred and fifty.

Adjourned.

Governor Altgeld and Dr. Dewey.—Commenting on Dr. D. H. Tuke's criticisms of the disgraceful application of the spoils system to Kankakee, the Chicago *Record* remarks: "If this abuse of political power is rough on the medical men who suffer dismissal, how about the public in general, which frequently loses at one swoop of the spoilsman's axe the benefit of an efficient medical officer's whole lifework and experience? The practice works harm both ways, and is a blot on American political usage. And the dismissal of Dr. Dewey by Governor Altgeld is recognized by the medical profession as a world-wide disgrace." Altgeld is the name of the man, and he should be remembered by all good Illinois doctors.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ROYAL COLLEGE OF SURGEONS—JUBILEE OF THE FELLOWSHIP—EXHIBITION OF RELICS OF JOHN HUNTER—CENTENARY OF HIS DEATH—ADDITIONS TO THE MUSEUM—CONVERSAZIONE—MEETING OF THE FELLOWS—ADDRESS OF THE PRESIDENT—POSITION OF FELLOWS AND MEMBERS—THE CROONIAN LECTURES AT THE ROYAL COLLEGE OF PHYSICIANS—USES OF NITRITES—SIR W. H. BROADBENT—SMALL-POX—ANOTHER FEVER HOSPITAL—APPROACH OF CHOLERA—THERAPEUTICS OF THE NITRITES—PROFESSOR LEECH'S CROONIAN LECTURES—USE OF NITRITES IN ANGINA PECTORIS—IN CARDIAC DYSPNŒA—ASTHMA AND BRONCHITIS—URÆMIC DYSPNŒA—HEADACHE AND MIGRAINE.

London, July 8, 1893.

The Royal College of Surgeons has been the centre of medical attraction this week. This is the fiftieth year since the institution of the fellowship, and the holders of that distinction have been celebrating its jubilee. This is also the one hundredth year since the death of John Hunter, and this centenary has been combined in the celebration. On the 5th inst. there was a most interesting exhibition of the Hunterian relics of the college, when besides these a number of exhibits were lent by their present owners, and so a most interesting collection was brought together. Some of Hunter's furniture and instruments were thus seen as cherished curiosities and memorials, though of course his great monument is the museum. But this also was made to combine in the celebration, as the additions made to it during the past year were on view, and will remain so for another week. Some of these specimens are unusually interesting, but they can be examined more leisurely after the Hunterian relics are again dispersed. I wonder if the owners of some of these will bequeath them to the college. It would be natural enough for the whole of them in course of time to find a permanent home there.

On Wednesday evening a conversazione was held at the college in honor of the jubilee. Nearly two thousand guests were received by the president and vice-presidents. The whole of the museum, including the recent additions, was thrown open, and presented a brilliant appearance. All the rooms were illuminated with electric lights, the ladies' toilettes gave lightness to the scene, and music and flowers added to the attractions.

On the 6th inst. a meeting of the Fellows was also held, when the President, Mr. Thomas Bryant, addressed the assembly. He said it was most appropriate that the Fellows should keep the jubilee of the institution of that grade. Some years before the charter establishing the fellowship was granted, the Council had wished to inaugurate such a change; but various circumstances delayed the proposal. In 1843, however, the new order was brought into being by the appointment by the Council, under the new charter, of 300 members to be Fellows. To these 242 were added in August, 1844, at the instigation of the government, to allay the discontent among members caused by the election, by mere favor of the Council, of a proportion of their number to a more privileged position. But agitation continued, as well it might, among the remaining members, until, in 1852, a supplementary charter was obtained authorizing the Council to appoint members of fifteen years' standing to be Fellows on the payment of ten guineas. The president said it was futile now to ask whether the wisest plan was adopted at the beginning. The fellowship is now obtained by examination, and is regarded as a most valuable surgical distinction. It confers also the privilege of electing the Council. And so the Fellows are rather an exclusive body, which the president seems to think quite natural. But, on the other hand, look at the position of members. They are the main body of the college; they supply the

funds; their influence is necessary to the college; if their diplomas are only licenses to practise, to call them members is an absurdity. But taking the president's statements, is it not clear that the new order filched all its privileges from the members? I believe the members will not be satisfied until they have a vote in their own college. The fellowship will be an academical distinction which will carry enormous prestige, and the Fellows may well give up their exclusive pretensions to govern the college.

On the same day, the 6th, the election of four members to the Council was held. Mr. Pemberton and Mr. Macnamara were re-elected, and Mr. Mayo Robson and Mr. H. Morris were chosen as new members. There were 134 Fellows who voted in person, and 390 proxies. Would it not be a much greater honor to be elected by 12,000 members?

The Croonian lectures this year were intrusted to Professor D. J. Leech, who took for his subject the action and uses of the nitrites and allied compounds. He related a number of experiments, and illustrated his lectures with tracings, formulæ, and graphic groupings. Only a few points in these interesting lectures can be referred to in a letter. The outcome of experiments on the heart muscle is that the molecules of the ONO group, in whatever combination, when present in even small amount, tend to quicken but to weaken the contractions. If the solutions coming in contact with the heart are very dilute, the quickening may make up for the weakening, and so the heart may do as much or even more work for a short time. But stronger solutions, after quickening, weaken, slow, and arrest the contractions. The evil influence of nitrites on the heart is evanescent if the nitrites be removed. Compared with the effect on muscle, nitrites affect other tissues much less. Even the tissues of the nervous centres seem to be less easily influenced. It has been shown that a solution of 1 to 5,000 has a marked effect on voluntary muscle, though its function in the living body is hardly disturbed. But the involuntary muscles and the heart are affected by marvellously minute quantities. Yet they do not seem to be permanently affected, and rapidly resume their normal function on the removal of the drug. They even seem less readily affected after repetitions of the experiment.

The nitrates in some conditions resemble the nitrites, but these seem to result from the reduction of the NO_3 group to the NO_2. In other respects there is a striking contrast between the actions of the two salts traced in all the metallic compounds. The nitrates exercise a powerful and long-lasting influence on the circulation in man. The action of a dose of ethyl nitrate is to lower the tension, which reaches its lowest point in thirty to sixty minutes; but the effect can be perceived for four or five hours—a striking contrast to the evanescent effect of the nitrite. This may be due to the fact that the nitrates are so much more stable. They seem, too, to cause a headache more often than nitrites, and this symptom may come on much later—may not appear for even four or five hours.

The Queen has conferred a baronetcy on Dr. Broadbent. Small-pox shows a further decrease. The Asylums Board has been authorized to secure another site for a fever hospital in the suburbs. Great efforts are being made to strengthen our defences against cholera, which is steadily advancing toward us. Our sanitary authorities seem alive to the danger, and confident of escaping.

London, July 14, 1893.

I have already sent you some account of Professor Leech's first two Croonian lectures. In the third and concluding one he followed up the subject of the nitrites from a therapeutical point of view, and to many this will no doubt be the most interesting. His first point was the minute quantities which affect the vascular system. An eighth of a grain of sodium nitrite, a fraction of a minim of ethyl nitrite, the sixteen-hundredth of a grain of nitro-glycerine will often affect the circulation. And yet, as a second point, considerable doses do not readily cause death. There seems to be no recorded case of death from ethyl or sodium nitrite. Amyl nitrite has been taken by the dessertspoonful, and yet recovery has taken place. In only a few instances has nitro-glycerine been fatal. The third important point is the evanescent character of the nitrite action. When nitrites do good their influence soon ceases, as it does when they do harm, and there is no cumulative influence. The cases, then, in which they are most likely to be useful are those in which the heart is embarrassed from a want of the normal relationship between its power and the calibre of the vessels through which it has to transmit the blood. Angina pectoris is the most conspicuous of this class of cases. A large proportion of anginal attacks seem due to a rise in tension, and this in turn is caused by a decrease in the calibre of the system or pulmonary vessels, and the consequent sudden call on the heart for increased propulsion, to which it is not perhaps able to respond on account of alteration in its walls. Other theories have been proposed, but Dr. Leech did not attach much importance to them. In reducing this tension we have three objects in view: 1, to relieve pain as rapidly as possible; 2, to avert a fatal end; 3, to prevent the recurrence of pain. The second object is attained when the pain is removed. The pain of angina varies much in duration; generally it is short in the earlier stages, and abates on the cessation of the immediate cause—generally movement. But later it may last several minutes and sometimes for hours. Propyl, isobutyl, and amyl nitrites reduce tension in a few seconds; sodium nitrite takes two to five minutes; ethyl nitrite about the same; nitro-glycerine forty seconds to two minutes. The inhalation of the fatty nitrites is thus obviously the most prompt remedy. The amyl nitrite in common use is a mixture of several nitrites, and should be replaced by a purer article, although the compound hitherto employed has been of the greatest service. In some advanced cases the remedy fails from its evanescence, and then we may resort to one of the nitrites having a more durable action. Although he regards these medicines as of the highest value in relieving and warding off attacks, Dr. Leech does not look upon them as possessing reliable curative properties. No doubt, if attacks can be prevented, recovery may take place, or at any rate, pain being removed, life may be prolonged, and the vessel walls may gain some advantage in their continual contest with the blood current. But it does not follow that the recoveries recorded after nitrites were caused by the medicine. The use of the nitrites is but one element in the treatment. They should be accompanied by agents which improve the state of the vascular system, among which iodide of potassium and arsenic hold the first place.

Next to angina the nitrites are of most use in cardiac dyspnœa. It may be thought that the rapidity with which the effect passes away tells against them in such cases, and this is so; but the good effect may remain to some extent, and the arteries which have been dilated by the dose do not contract again the moment the drug is withdrawn.

In syncope and heart failure it is more difficult to determine the propriety of using nitrites. The heart will be relieved of part of its work, and beat more quickly under their influence; but it is not easy to graduate the dose to the necessities of the heart, and a quantity thrown into the circulation by inhalation might easily stop a failing heart. In pulmonary dyspnœa many cases have been recorded as benefitted, and in asthma and bronchitis there is a field for the use of the nitrites. They may relieve the dyspnœa, but can hardly be expected to be curative. In uræmic dyspnœa the use of nitrites is still less effectual. In migraine and headache small doses may be tried, as then they can be repeated if without result. A large dose should not be given, as, if useless, the effect will be very unpleasant.

A Nurses' Co-operative Club has recently been formed in London.

OUR BERLIN LETTER.

(From our Special Correspondent.)

PROFESSOR LIEBREICH VERSUS KOCH—BEHRING'S DIPHTHERIA-HEALING SERUM—FOOT-AND-MOUTH DISEASE IN HUMAN BEINGS—THE TREATMENT OF EPITHELIAL CANCER WITH ARSENIC.

BERLIN, June 25, 1893.

AT no time has there existed such a sharp controversy regarding Koch and his followers as now, and if matters continue as they exist at present we may possibly live to see the end of Koch's discoveries. Professor Liebreich, the renowned pharmacologist, is the latest opponent of these investigations. In a paper entitled the "Methods of Examining Cholera Dejecta" he finds totally different results from those heretofore published and accepted by Koch. So, for example, in speaking of peptone cultures, Liebreich claims they are unreliable, as the preparations of peptone have a curious and at times different combination.

So also the cholera red reaction is not characteristic of cholera cultures, as claimed. When other bacteria were present in conjunction with cholera vibriones, the reaction did not take place in a peptone culture.

The animal experiments were also found to be unsatisfactory, especially the method called "infections modus," as described by Koch, wherein he neutralizes the gastric juice by the addition of soda solution and paralyzes the intestinal peristalsis by injections of opium. These experiments were usually conducted on guinea-pigs.

The method of Pfeiffer, of bringing a culture into the abdomen and thus producing a characteristic clinical picture is discredited, as the same symptoms can be produced by introducing other than cholera bacteria. Especial attention is directed by Liebreich to the way in which Pfeiffer introduces his inoculations. Liebreich claims that as Pfeiffer uses the amount of a culture that clings to a platinum needle, this conflicts with the morphological characters of the comma bacillus as described by Koch.

Liebreich believes that the cholera bacillus of India is entirely different from that causing cholera in France and from the one found in Germany.

Koch stated that the comma bacillus of India leaves milk unchanged, whereas this is decidedly untrue as regards the bacilli found in France and Germany. The form of the cholera vibriones varies according to different investigators. B. Fischer, of Kiel, who accompanied Koch to Egypt and India, found that the comma forms change at times to rod-shaped bacilli, and Finkelburg states that they assume other forms than the above.

Peter, in Paris, insisted a long time ago that bacilli will frequently change their shape and assume "comma" forms. A very important point is the fact that people who were apparently in perfect health were found on bacteriological examination to have numerous comma bacilli in their intestines. Further, Liebreich strictly opposes the ideas embodied in the treatment of disease by means of blood serum, and declares the only rational method of treating disease is based upon the so called cellular doctrine of Virchow, because our organism is built up by cells, and it is here that a disease producer or generator must first cause a weakened function, the interference of which gradually manifests itself in the usual way.

Pigeons are ordinarily immune against anthrax, but if we permit them to hungerize, to weaken the "vitata fungie" of the cells, we find the former immunity disappearing and infection occasionally taking place. Professor Brieger, a prominent disciple of Koch, and a well-known bacteriologist, has branded Liebreich's remarks as full of mistakes. Liebreich's paper excites here much comment, since it is the first of its kind to criticise Koch's method, which has until now withstood the test of time. A reliable informant tells me that Koch will answer Liebreich in detail as soon as he receives the stenographer's copy of the lecture. I shall not fail to give your readers Koch's answer, which is anxiously expected.

Besides cholera, diphtheria and its so called serum treatment invite continued attention. Professor Behring, assistant in the Koch Institute, has been occupied continuously with the question of the treatment of diphtheria. From his latest work we review the following: "In the last few months thirty cases of diphtheria have been treated with the 'heil-serum.' In all cases diphtheria had been positively diagnosticated. More especially in the Institute for Infectious Diseases, every case that did not contain diphtheria bacilli was excluded. Of these 30 cases 24 were cured and 6 died, giving a mortality of twenty per cent. These numbers are yet too small to justify positive conclusions, but seem to encourage the application of the treatment on a larger scale.

"The serum was introduced with a Koch's hypodermic syringe containing 10 c.c. of the fluid, and was chiefly injected under the skin over the pectoral muscles. Gentle massage allows the introduction into children of 20 c.c., with but slight distention of the skin in the vicinity of the injection. The skin does not show any general reaction, but a mild form of sensitiveness remains for a few days. There is, however, no visible influence on the local inflammatory process in the form of a local reaction. Judging from present experiences, the serum does not show any detrimental influence on the body. There are three distinct results aimed at by this therapeutical method: 1. The prophylaxis of the disease if the serum be applied before the appearance of characteristic symptoms. (This has been demonstrated in numerous experiments with animals.) 2. The arrest of the development and of the further progress of the disease. 3. The transformation of severe and advanced infection into a mild form of the disease, resulting in speedy convalescence."

This healing serum is as yet not supplied to private persons, to physicians, or even to hospitals, the means not being at hand for its production in sufficient quantity. The present supply of serum is being used up by certain specified hospitals—in Berlin at the children's department of the Institute for Infectious Diseases, where children suffering with diphtheria are taken as the number of beds permits.

Besides Behring, a young Berlin pædiatrist, named Hans Aronsohn, has published the results of experiments with healing serum which appear to go far beyond the results obtained by Behring, providing they can be substantiated. Aronsohn claims to have discovered a process by which a solid form of serum is produced one hundred times as effective as that made by Behring. According to Aronsohn's experiments on guinea-pigs, diphtheria-infected children weighing about ten kilogrammes can be cured by the application of several decigrammes. The speaker further hoped to be able during the next few months to cultivate such a large quantity of this antitoxine that many children can be treated by it.

Dr. I. Boas read a paper before the Society for Internal Medicine—"The Existence of Foot-and-Mouth Disease in Human Beings." It has been known for several decades that this disease can be transmitted from animals to man, but a true clinical picture of the method of its transmission, the author said, was wanting.

Two years ago Dr. Siegel, of Britz (near Berlin), made some clinical and bacteriological investigations during a very severe epidemic, which are rather conclusive. Dr. Boas, in conjunction with Dr. Siegel, examined a number of recent and chronic cases of foot-and-mouth disease, and gave the following description of it: The period of incubation lasts from eight to ten days, and beyond a feeling of lassitude offers no characteristic symptoms. The prodromal stage is marked by chills, a general sensation of fatigue, dizziness, pains in the lumbar region and drawing pains in the muscles of the limbs. At the height of the disease they found a temperature of 38° to 38½° C. (100.4° to 101.3° F.), in children 39° C. (102.2° F.), and more frequently an enlargement of the liver with tenderness on pressure, but no enlargement of the spleen. After the fever subsides a peculiar eruption appears on the lips especially, on the cheeks, mouth, and

mucous membrane of the tongue, which has the characteristic of stomatitis aphthosa. This is accompanied by swelling and œdema of the tongue.

In one severe case the tongue was so swollen that it was pushed out of the mouth, and part of it was lost by necrosis. In this same patient a swelling of the masseters took place, and he is at present unable to open his mouth and to masticate his food, although it is three years since he contracted the disease.

Along with this mouth affection there is frequently an exanthematous eruption, appearing sometimes in a simple form, sometimes in the form of petechia, sometimes as blisters like those in pemphigus. As soon as the eruption appears the fever subsides, the appetite returns, and convalescence ensues. In some cases, however, severe complications appear, as in scorbutus; severe mouth, stomach, and intestinal hemorrhages; convulsions, in children, and frequently, also in children, catarrhal pneumonia. Several hundred were treated and only twenty ended fatally.

As an etiological factor Dr. Siegel finds a special bacillus, and is still engaged in cultivating pure cultures and experimenting on animals.

Besides this acute form there exists a chronic condition, manifested by weakness, anorexia, tenderness in the region of the stomach and liver, lasting several weeks. The lecturer witnessed an epidemic of foot-and-mouth disease in a Berlin family. They drank raw milk, which they procured from a farm where an epidemic of the disease had existed. He furthermore said that this interesting infectious disease will tend to explain certain dubious cases of gastricism, febris gastrica, and other cases in which a diagnosis was uncertain.

Dr. Lassar, a dermatologist of Berlin, recently read a paper before the Berlin Medical Society on "The Treatment of Epithelioma with Arsenic." He recommends the use of five drops each of Fowler's solution and spirit of peppermint, three times a day. He showed wax models of patients, which demonstrated the good effects of the remedy. In the discussion following, Dr. von Bergmann intimated that according to his experience a cure of epithelial cancer may take place under indifferent treatment. The ideal treatment of epithelioma, as that of all cancers, is removal by the knife. Only in inoperable cases could a trial of Lassar's remedy be applicable.

New Instruments.

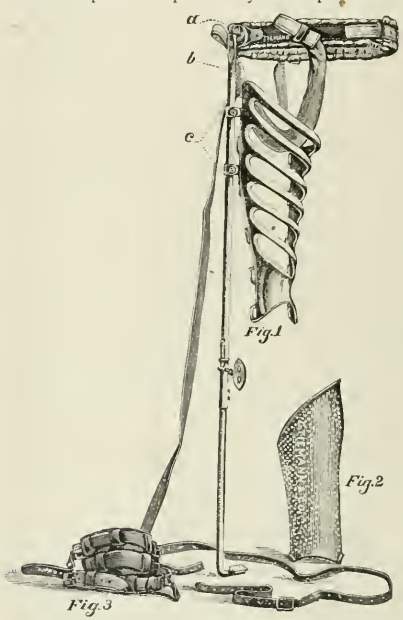
A NEW SPLINT FOR TREATING FRACTURES OF THE FEMUR WITHOUT CONFINING THE PATIENT TO BED.

By J. S. PYLE, M.D.,

CANTON, O.

It has been my experience to meet with difficulty in treating, to my own satisfaction, fractures of the upper third of the femur. With few exceptions, all the old dressings fail to keep the limb in position when the body is moved, and consequently it requires close attention to secure a good result. The confinement and necessity of restraining the movements of the body are very objectionable to patients, and any measure that will do away with this feature will be acceptable. I have succeeded in doing this, and, in addition, afforded correction to other defects that were always present to a great degree.

The thigh in the upper third is not cylindrical, and anything that would girdle the limb changes the contour, and to this extent offers the greatest hindrance to coaptation of the broken fragments. A perfect dressing should restore the natural boundaries, and properly support the seat of fracture. Many of the dressings are minus these features and are worse than nothing, inasmuch as they add to the weight of the limb and do not assist in maintaining reduction. The familiar plaster-of-Paris dressing is an instance. The plaster bandages are rolled on the thigh, over perhaps coaptation splints, and carried up to the perineum just on, or a little above, the seat of fracture. Usually, with the weight-and-pulley appliance, this completes the dressing. If the plaster bandage should be carried over the groin in the form of a spica to obtain further support, it soon breaks and is found of no assistance, but adds greatly to the discomfort of the patient. Every time the patient moves there is a corresponding movement at the seat of fracture, and the extension appliance, with the patient's restlessness, operates continually in getting the shaft of the bone out of alignment. In this condition the broken bone is allowed to remain until repaired. These reasons appeared to me to make the greatest demand for an appliance that would supply a perfect support, immobilize the seat of fracture, and in addition improve the portability of the patient.



In Figs. 1, 2, and 3 the apparatus is represented, which is seen to consist of an anterior and a posterior splint, knee-girth, pelvic girth, perineal band, and an extension rod with vertical support. The latter, with certain modifications, answers the description of Sayre's long hip-brace. The forward and backward movement of the vertical rod at the hip-joint is prevented, but abduction is allowed. The steel pelvic girth encircles the body below the crest of the ilia, the object of which is to prevent any movement of the thigh when the body above the lumbo sacral articulation is shifted. This is essential. If the girth encircled the body above the ilia it would necessitate the movement of the thigh every time the trunk changed its position. In the present arrangement this is prevented, and the upper part of the body allowed free movement without altering the position of the broken limb whatever. The vertical support and extension rod are made of the best steel. The former is a piece of steel tubing 26½ inches long and 5/8ths of an inch in diameter, containing the extension rod, both being so proportioned in length as to be adjustable to a person of any size. At the upper end of the tubing a short steel rod 3½ inches long, and of the same diameter as the tube, is hinged to the pelvic girth so as to allow abduction. The lower end is turned, leaving a shoulder, which makes a joint with the steel tubing at *b* in Fig. 1, where the posterior splint can be taken on and off when occasion requires. The joint is made secure by means of a screw. The extension rod is operated by a key and rack,

and at the lower end bent at right angles, bearing a rotary steel plate used as a fastening to the under surface of the shoe. The splints are made of copper and aluminum. The posterior splint is the principal support, and is an aluminum casting weighing two pounds. The pattern for the casting was obtained from a plaster mould of the thigh. In this way it was possible to secure a splint bearing the exact figure of the thigh throughout its whole extent. It was thought best for the sake of lightness to have it ribbed. The same support is obtained, and at the same time the surfaces and curves corresponding to the thigh are maintained. The upper rib was traced along the gluteal fold, reaching on the outside above the trochanter major. From this it will be seen that every portion of femur is supported. The ribs take a spiral course and reach the level of the abductors and gracilis on the inner side. Two-thirds of the circumference of the thigh is enveloped by the splint, and it extends as low as the origin of the soleus muscle on the leg. The lower end of the splint is solid, and its inner surface is a fac-simile of the posterior surface of the knee-joint. The splint is fastened to the vertical support by means of two bands, which can be tightened or loosened, allowing the splint to be moved up or down at will. This allows it to be adjustable. Along its inner and outer borders the splint is provided with slots for lacing straps, which is shown in Fig. 4 with lacer adjusted.

Fig. 5 shows the posterior surface of the thigh with the splint applied. Fig. 2 illustrates the knee-girth, which, in its application, is strapped to the knee independent of the splint. The straps running along the upper and lower borders, secured by retainers, are buckled into the two lowest slots on each side of the posterior splint. Securing the knee in this way prevents any rotation and keeps the limb straight.

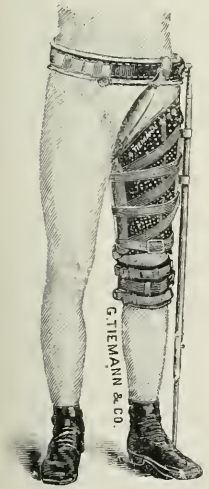


Fig. 4.

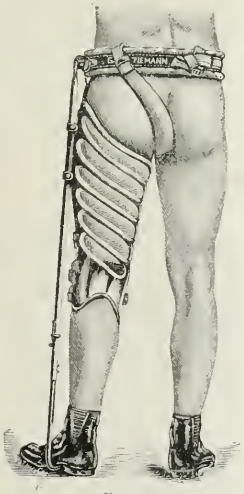

Fig. 5.

In Fig. 3 the anterior copper splint is represented, which is a counterpart of the posterior splint, but made to fit the anterior half of the thigh, extending from the inguinal fold to within a few inches of the patella.

Figs. 4 and 5 show the various parts of the apparatus applied to a broken thigh. These illustrations, which are reproductions from photographs, show how thoroughly the thigh is supported. It will be seen at a glance that the splint allows the greatest freedom to the movements of the body, without in any way disturbing the seat of fracture. The patient is at liberty to change posture, requiring no assistance, and can be placed upon the bedpan or allowed to go about with the aid of a crutch, without having any fear of doing injury to the broken bone.

The anterior and posterior splints are made in three sizes and for both limbs. The patterns have been placed in the hands of Messrs. Tiemann & Co., of New York, where the splint can be seen and obtained by parties desiring to purchase. Owing to the difficulty in its manufacture, no one but Tiemann has been authorized to make them. In the construction I wish to express my obligations to Mr. C. B. Miller, foreman of the Canton Surgical Chair Works, for the excellent workmanship and patient care exercised in executing my ideas.

68 West Tuscarawas Street.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 29, 1893.

	Cases.	Deaths.
Typhus fever	0	1
Typhoid fever	22	7
Scarlet fever	45	4
Cerebro-spinal meningitis	11	14
Measles	185	9
Diphtheria	74	36
Small-pox	2	2
Cholera	0	0
Varciella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

The Vertigo of Arterio-Sclerosis.—Dr. Church calls attention to arterial disease as a neglected, but nevertheless very frequent, cause of vertigo. When a man past the prime of life, without any previous serious illness, suddenly becomes faint, has a swimming in the head, a feeling of giddiness, of distinct gyration, of darkness and impending death—one or several of these sensations—he usually at once seeks advice, in grave apprehension—sometimes well founded—of cerebral apoplexy, and usually gets a cholagogue cathartic, or is told that his stomach is wrong, and sometimes is told so rightly (*The British Medical Journal*). But cases are constantly presenting themselves in which such vertiginous attacks are happening at shortening intervals. The patient gives up his tobacco, his spirits, if he is a drinker, cuts down his meat, takes to some of the many waters recommended, has Turkish baths, and gains only moderate relief or none at all. If carefully examined, he will be found to have a well-defined tortuous frontal artery, a distinct arcus senilis, a clanging second sound of the heart, a pulse of increased tension, and scanty urine, with perhaps a trace of albumin. He finds that exertion of a moderate amount precipitates the attack, that he cannot endure a temperature at all above the usual, and often a change of position from recumbency to the upright is the occasion of giddiness. The attack is often accompanied by a fulness and throbbing in the head, a feeling of heat in the scalp, a blur before the eyes, and transient pallor of the face. In the treatment of this affection iodide of potassium is the sheet-anchor, and is given in doses varying from thirty to ninety grains a day for months, sometimes with the result of effecting a complete cure.

Medical Ethics in Life Insurance.—The editor of the *Pacific Medical Journal* tells some very caustic truths when he says that it is a common custom for the medical director or medical examiners of life insurance companies to write to the family physician, or physician who may have attended an applicant, for his opinion as to the applicant's physical or mental condition. The medical director generally attempts to convey the idea to the family physician that by giving his opinion to the company he is conferring a favor upon the applicant. Now,

what are the facts of the case? The company is anxious to get new business; it offers a runner or so-called agent an enormous percentage for any new risk that he can procure; the runner talks, that is, often lies a man into making an application for a policy; he has the company's medical examiner pass upon the case; there is something doubtful about the risk and the company wants the opinion of the family physician who knows all about the case. Now, will any one kindly explain why the company should not pay the family physician for his opinion, or why the family physician should give his opinion for nothing? Who is to be benefited by the transaction? the company and runner, of course; that is what the officers of the company are doing business for, to make their own fortunes and live like princes. The family physician's opinion may be worth hundreds or even thousands of dollars to the company by either enabling it to avoid a risk upon which it would lose thousands of dollars or by enabling it to take a large risk that will pay several thousand dollars annually, and to carry which will cost the company as many hundreds. We recently have adopted a plan that we can recommend to our readers with that absolute and positive assurance that it is born of experience, viz.: When the runner or life insurance director writes to you for your opinion of an applicant who has been examined by the company's examiner, write to the medical director that you require two conditions before you can comply with his requirement: that he send the permission of the applicant and a fee of $25 for your written opinion. This is simply a plain, common-sense business transaction. There is nothing in medical ethics to require you to give the medical company's medical director your opinion for nothing; it is your professional opinion the company wants and they want it for business purposes. Charge as you would charge any other corporation for medical services rendered. Do you suppose that if the company's attorney wanted the opinion of an outside lawyer he would think of asking him for gratuitous services? Furthermore, is it proper, even with the applicant's permission, to divulge certain facts which have been acquired in the pursuit of professional investigation? May there not be some little points known only to his medical attendant and which he would strenuously object to being divulged were he aware of their existence? The entire question is one worthy of serious attention and thought on the part of every conscientious practitioner.—*Medical Review.*

The Successful Specialist.—Within a month we have been told by three fresh graduates that they were going into the field as "specialists." Let them heed the words of those best able to judge. Dr. Joseph Price has lately said: "The successful specialist must have several years of active general practice. It is in it he gains his first and best lessons in practical obstetrics and in the diseases peculiar to woman. It is in this general practice he first encounters the one among many gynecological difficulties, that of rational diagnosis."—*National Medical Review.*

The Discomforts of an Albino.—An autobiographic chapter of the recently published life of Lord Sherbrooke (*British Medical Journal*) gives an interesting, although not altogether accurate, account of his sufferings as an albino, a misfortune which he shared with an older sister. His description is as follows: "The peculiarity of my eyes consists in the total absence of coloring matter; this occasions, of course, especially in a man, a very marked peculiarity of complexion, amounting in early youth to something of effeminacy. For this evil, however, I have found age a sovereign cure; but as the absence of coloring matter extends to the eye, it necessarily occasions a great impatience of light. The eyelids must always be nearly closed, and so I have never been able to enjoy the luxury of staring anyone full in the face. Of course this intolerance of light must be attended with something very closely approaching to pain. I cannot even conceive the state of a person to whom sight is a function free from all pain and distress; but as I have no standard to measure by, I may exaggerate my own misfortune. The cause of this annoyance is the total absence of what is called the pigmentum nigrum, the dark rim which surrounds the pupil of the eye and absorbs the rays of light which are not needed for the act of vision, and only confuse and disturb it. But, in addition to this defect, I had to contend with a malformation of the eye; one eye has never been available to me for reading, and the other was hypermetropic—that is, the refracting power was so slight that the focus must be very near the back of my head. I began life, in fact, very much in the state of persons who have been couched for cataract, with the additional disqualifications that I had only one eye to rely upon, and that had no pigmentum nigrum to protect it." This account is of interest as that of an educated observer without medical knowledge. The degree of "impatience of light," as Lord Sherbrooke rather aptly puts it, varies considerably in albinos, and some are able to pursue ordinary avocations with comparatively little discomfort. The absence of pigment referred to by Lord Sherbrooke, is not, of course, confined to the "dark rim surrounding the pupil," but extends to the whole of the uveal tract, iris, ciliary body, and choroid, and this absence renders the iris more or less diaphanous.

Inspection of Emigrants at Liverpool.—The New York *Sun* says that Dr. H. L. Williams, United States Inspector of Emigrants at Liverpool, is being denounced in the local press for the undue severity of his methods, from which it may be reasonably assumed that he is doing his duty to his Government. The Liverpool Poor Law Guardians, at a recent meeting, declared that Dr. Williams turned back from the Etruria, as suffering from small-pox, a man who had that disease in December last, and was discharged from hospital as cured in January; but the doctor denies this. At the same meeting an unconscious compliment was paid to Dr. Williams and his assistants by the sorrowful admission that, owing to stringent inspection, scarcely any attempts were now made to smuggle undesirable emigrants off to America, and that even the shipping companies had become exceedingly cautious. The Government has called for a return from the port authorities of persons made chargeable to the Poor Law Guardians in consequence of the American emigration regulations. It is believed the number of such cases is very small.

Diagnosis of Hysterical Epilepsy by the Urine.—Dr. Gilles de la Tourette, writing in a Belgian journal, urges surgeons before operating on epileptic patients to make a careful examination of the urine. He states that by that means a diagnosis can be made between partial hysterical epilepsy and partial epilepsy due to a neoplasm; for, according to researches made by him in conjunction with Dr. Cathelineau in Professor Charcot's clinic, when the epilepsy is due to a tumor there is a marked increase during the fit in the urea and the phosphates, while in hysterical epilepsy these bodies are excreted in smaller quantities than usual during the attack.

Biborate of Soda in Epilepsy.—This remedy, first recommended in this country by Dr. Gowers, has been subjected to an extended trial by Dr. Mairet. He finds that toxic effects are produced, such as gastric disturbance, œdema of the extremities, loss of hair, conjunctivitis, etc., in nearly all the cases. He recommends small doses to begin with—from eight to fifteen grains daily—gradually increased to sixty or seventy. His maximum dose was from one hundred and fifty to one hundred and eighty grains daily, but when the attacks are not affected by one hundred and twenty grains daily no good is to be obtained from the remedy. After the effective dose has been reached the quantity should be gradually reduced. The mental state he found not to be affected, even with pro longed administration, but he did not consider that the good effects were sufficient to outweigh the disadvantages of the remedy.

REPORT OF A CASE OF SARCOMA OF THE CERVICAL SPINAL CORD; AUTOPSY.

By WILLIAM H. ROSS, M.D.,

BRENTWOOD, N. Y.

LATE HOUSE PHYSICIAN PRESBYTERIAN HOSPITAL, NEW YORK.

Cases of sarcoma of the spinal cord are of such unusual occurrence that it seems desirable to make a report upon the following instance of this condition, in which a careful record of the clinical history is supplemented by an examination of the spinal cord.

R W——, aged 29, single, merchant, resident of Long Island, was in good health until the beginning of the present illness, barring occasional attacks of chills and fever, and during the past two or three years repeated and prolonged colds, which ended in cough lasting several weeks. The patient has never used alcohol even in moderation, and it is stated by his father that his habits have been in every respect exemplary. The family history is quite negative.

The first evidences of the present trouble appeared about May, 1891. At this time the patient noticed a loss of sensation, beginning as numbness, in the ulnar side of the little finger of the right hand. This sensory loss soon extended to the entire little finger and thence to the ring finger and ulnar side of the middle finger. At the same time there was an upward extension of anæsthesia along the hand. Three months from the onset the anæsthesia had passed up the ulnar side of the forearm and arm, and had reached outward over the hand as far as the thumb.

Soon after the sensory loss made its appearance the patient began to have pain in the ulnar side of the right forearm and hand—slight and occasional at first, later very severe and of increased duration.

After the anæsthesia and pain had become established, loss of power was observed, first in the flexors of the finger, then in those of the forearm. The loss of power increased rather rapidly in degree and extended gradually up the right arm. About five months after the first symptoms were noted there developed atrophy of the first dorsal interosseus. Soon after, the muscles of the thumb and of the hypothenar eminence began to undergo wasting. The atrophy gradually became very pronounced in these situations and extended to the flexors of the forearm. The pain referred to above increased gradually in severity until about the eighth month from the commencement of the symptoms. At this time the patient noticed that the muscles of the right arm and forearm were very stiff, and interfered with the movements produced by the action of the unparalyzed muscles. The period during which the pain was at its height, and the arm was the seat of pronounced rigidity, lasted about six weeks. The pain then abated very much and was subsequently a distinctly less marked feature of the disease. During the period of severest pain the entire right arm became œdematous The œdema was exceedingly variable in degree, being at times pronounced, at others slight. The degree of œdema was not observed to bear any definite relation to the severity of pain.

A careful physical examination was made in June, 1892, about thirteen months after the beginning of symptoms. The patient was noted to be a man of medium height and slight build, and considerably emaciated. The right arm hung flaccid from the shoulder, apparently powerless. Upon effort it was possible for the man to abduct the arm slightly. No other motion was possible in the arm. Passive abduction of the arm to the horizontal position was impossible, owing to a rigid contracture of the pectoralis major and the muscles at the back of the shoulder. The fingers of the right hand were in extreme flexion, and the wrist was flexed upon the forearm. By making extreme passive flexion of the wrist the fingers could be slightly extended from their cramped position. The wasting of the right arm was very conspicuous. The muscles of the thumb and little finger and the interossei were greatly atrophied. The right forearm in the middle one-third was one inch smaller than the left at the corresponding level. In its lower third the right forearm was one-half inch smaller in diameter than the left. The upper arm was about one-half inch smaller in diameter. The right deltoid showed slight wasting.

The electrical examination showed loss of faradic irritability in the right arm, in the deltoid, biceps, triceps, and all the extensors and flexors of the wrist and the interossei. Very slight irritability remained in the supinator longus.

Tactile and pain sense were entirely lost along the ulnar border of the arm to the axilla, and were greatly impaired along the radial border as high as the shoulder. Temperature sense was only roughly tested. It appeared to be quite lost in the arm. There was almost entire loss of the muscle sense in all the muscles of the right arm. The patient had no sense whatever of the position of the fingers, hand, and forearm.

The surface of the right arm was much colder than that of the left. It was pale in color. From time to time there was considerable pain in the right shoulder.

In the left hand and arm, power and sensation were apparently normal. The grip seemed a little weak, but this may have been owing to the patient's debilitated state. Both legs were a little weak, and about equally so. Sensibility in the legs was normal, and there was no complaint of pain. Equilibrium was maintained without any difficulty, except the oscillation due to rapid fatigue. The knee-jerk was much increased upon both sides, but the exaggeration was most pronounced on the right side. Ankle-clonus was readily obtainable upon both sides, but was more prolonged upon the right.

The power of the sphincters was unimpaired.

It was apparent on inspection of the patient that the head was fixed rigidly upon the shoulders, inclined slightly to the right side and rotated somewhat to the left. Passive movement of the head in any direction caused pain in the shoulder and arm. There was no vertebral deformity and no tenderness on pressure over any of the cervical or upper dorsal spines.

The heel and toe test did not cause pain in the neck.

The movements of the tongue and lips were normal. Sight was unimpaired. The right palpebral fissure was distinctly smaller than the left, and the right lid drooped a little. The pupils reacted normally to light and during accommodation. The right was a little smaller than the left. When the patient reads, the right eye waters so freely that he has had to give up reading.

During the winter of 1892 the patient received a single hypodermatic injection of morphine of unknown strength. He states that this was followed in about fifteen minutes

by numbness in the entire right side of the body, including the head. This condition of numbness persisted for one month, and the patient thinks the contraction of the right pupil, the drooping of the lid, and the watering of the eye date from the time of the injection.

An examination of the chest showed dulness on percussion over the upper part of the right side. The vesicular murmur was weak over the right chest in front and behind, with expiration prolonged. A few subcrepitant râles could be made out upon the right side over the upper chest.

Temperature 101°, pulse 100, respiration about thirty per minute.

In the course of two weeks after the examination recorded above, the right leg became much weaker than before, and pain and numbness extended gradually down the entire left arm. Two weeks later considerable loss of power was detected in the left leg. There was also noted slight tactile loss below the knee. About this time the patient developed temporary retention of urine, and the already existing constipation became more pronounced. There was developed in the right arm pronounced œdema, associated with considerable pain. After a week these symptoms passed gradually away. On July 24, 1892, that is, about a week after the subsidence of the pain and œdema just noted, there was observed a tense swelling over the outer end of the right clavicle and extending down into the axilla over the front of the shoulder.

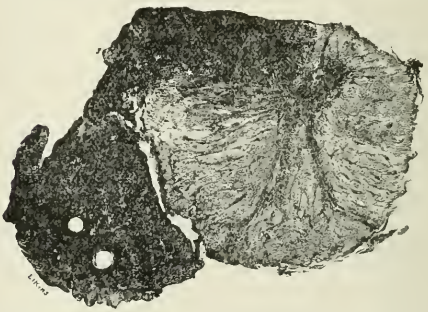
In the course of two weeks this tumor grew to the size of a child's head, became very tense, and was covered by greatly distended veins. The patient now grew rapidly worse. Incontinence of urine and fæces set in, and breathing became labored owing to paralysis of the thoracic muscles. It was observed at this time that total loss of sensibility extended as high as the crest of the ilium upon both sides, and that sensibility was greatly impaired bilaterally as high as the third rib. Unfortunately, no detailed studies of sensibility were made at this period. Large bedsores now appeared, and on September 12, 1892, sixteen months after the beginning of symptoms, the patient died from exhaustion and respiratory failure.

Autopsy.—The autopsy was a partial one. The right chest was opened, and from it were obtained a mass from the clavicle and another from the upper and posterior part of the thoracic wall. The upper part of the right lung was displaced by a number of tumors which occupied the posterior and inner aspects of the right upper chest. Some of those masses appeared to grow from the clavicle, others from the vertebræ, but their relations could not be distinctly made out. The following pathological report is by Dr. C. A. Herter, of New York, who saw the patient in consultation:

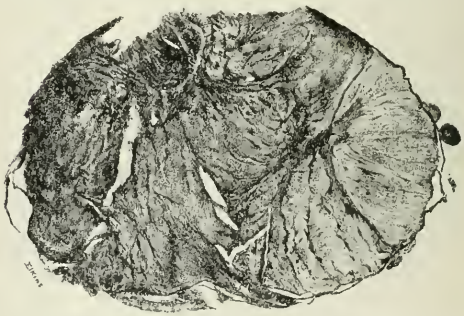
The specimen obtained from the spinal cord was five inches long, and extended from the eighth cervical to the seventh dorsal segments, both inclusive. On the right anterior aspect of the upper end of the specimen is a mass, one and three-sixteenth inches in vertical extent and one-half inch transversely, extending downward beyond its attachment to the cord. The mass is firm in consistence, and encloses the right anterior nerve-root of the eighth cervical segment. Unfortunately, the uppermost part of the tumor was not obtained. Sections were made from the eighth cervical, and first, second, and third dorsal segments. The degree of encroachment of the tumor upon the cord at the level of the first dorsal segment is shown in the accompanying photograph. It is seen that the tumor involves at this level nearly the entire right half of the cord, and encroaches anteriorly upon the left anterior column of the cord. Posteriorly, it does not pass quite to the posterior horn. At the level of the eighth cervical segment the size of the tumor in transverse section is about the same as at the first dorsal level, and the area of cord involved is approximately the same. At the second dorsal level the invasion of the cord by the tumor is limited, in gross appearance, to the right anterior half of the cord. The tumor does, however, extend across the median line by way of the commissures as far as the inner border of the anterior horn of the left

side. In the third dorsal segment the cord again presents a normal appearance.

In structure the tumor is an exceeding vascular spindle-celled sarcoma. Unfortunately, its exact relations to the membranes of the cord cannot be made out. It appears to have extended to the pia of the right side from the nerve-roots of the eighth cervical segment, and from the



pia to the right half of the cord and to part of the anterior columns of the left side. The nervous structures included in the right half of the cord are all but obliterated; all that remains of nerve-elements is a small number of partially or completely degenerated nerve-fibres, scattered irregularly through the tumor tissue.



On the left side of the cord, at the level of the eighth cervical and first dorsal segments, the anterior horn is contracted from side to side and contains no normal ganglion-cells. In the second dorsal segment a few ganglion-cells have escaped damage, but even here the great majority have undergone partial or entire destruction. In some instances the ganglion-cells have been apparently replaced by small groups of spindle-shaped

connective-tissue cells, connected with the anterior horn by large vessels extending along the thickened connective-tissue septa to the periphery of the cord, where there lies a layer of fibrous tissue between the substance of the cord and the pia, infiltrated and thickened with small spheroidal cells. The anterior horn itself is supplied with vessels excessive in size and number, and surrounded with abundant nuclei. It is evident from the appearances that the extension of inflammation to the anterior horn has been in part along the vessels radiating from the periphery, in part from direct extension along the gray commissures from the tumor upon the right side. It is interesting to note the preference of the foci of inflammation for the more vascular gray substance. There is no evidence of secondary myelitis about the tumor, except the appearances just noted, which are probably in some manner connected with the extension of the growth itself. Sections below the tumor give no evidence of secondary degenerations.

Sections made from the masses obtained from the clavicle and thoracic wall show them to be fibro-sarcomata.

Observations.—In the foregoing case the relation between the symptoms and the pathological findings is sufficiently plain.

The earliest symptoms in the case were pain and anæsthesia in the ulnar side of the right hand. These symptoms may safely be referred to the partial destruction and irritation, by the tumor, of the right eighth cervical nerve, probably in the intervertebral foramen or just external to it. The loss of power and atrophy in the muscles of the hand and forearm are referable to the further invasion of the nerve-roots of the right side of the eighth segment, and to the invasion of the gray matter of the cord at and just above this level. The ultimate diminution in irritative symptoms in the right arm, especially pain and rigidity of the muscles, correspond to the stage of the invasive process where irritation is replaced, through further growth of the tumor, by an essentially destructive condition. The involvement of the leg upon the same side as the arm is referable to the extension of the process to the lateral column of the cord. In giving this explanation we are assuming that the neoplasm, in extending to the cord, developed with preference in the gray matter. This view is justified by the evident preference for the gray substance seen upon the left side of the cord, where the morbid process is just invading the anterior horn.

The loss of power which, late in the course of the process, extended to the left leg and to a less extent to the left arm, may be regarded as depending not upon the actual invasion of the left half of the cord by the sarcoma, but upon the pressure to which this part of the cord was plainly subjected by the growth of the tumor upon the right side. In evidence of this we may call attention to the reduced size of the left cord, and especially to the very close approximation of the two posterior horns. Further, the foci of inflammation in the left anterior horn, to which allusion has been made, do not explain the total absence of ganglion-cells from the anterior horn at the level of the tumor. This loss is most reasonably to be regarded as the consequence of impaired nutrition of the gray matter in its most differentiated elements, this being in turn the effect of lateral pressure.

The marked œdema of the right arm is a symptom of interest, especially as it does not appear, judging from the records of cases, to be of very frequent occurrence in tumors of the cervical cord. It seems probable that it depends upon implication of vaso-motor paths in the central gray matter, as suggested by Remak in the case of syringomyelia.

The contraction of the pupil and of the palpebral fissures upon the side of the tumor is to be explained as the consequence of paralysis of the dilator sympathetic fibres that are thought to originate in the lower cervical and upper dorsal cord. The drooping of the lid doubtless depends upon relaxation of the fibres of Müller.

These ocular symptoms appear to be not infrequent in cervical cord tumors. They have been often noticed by Thorburn in crushes of the cervical cord. Where the cord is bilaterally injured the ocular symptoms are correspondingly bilateral. I have met with unilateral ocular symptoms in a case where one side of the cervical cord was crushed and the other only slightly damaged. There is good reason to believe that the symptoms require for their production a considerable degree of damage to the gray matter of the cord.

Regarding the diagnosis in the case recorded, it may be said that the anatomical diagnosis presented no difficulties. The indications were those of a focal process involving the right half of the cord in the region of the eighth cervical segment, and extending a short distance above and below this level. The pathological diagnosis was made with hesitation. The presence of signs of consolidation, muco-purulent expectoration, hectic temperature, rather rapid emaciation, and night sweats all suggested a tubercular process, and the diagnosis of a secondary tubercular tumor of the cord was thought to be justified. The alternative diagnosis was sarcoma, but it must be owned that this appeared improbable. An examination of the sputum would probably have settled the question, but was unfortunately not made. As the pathological diagnosis was incorrect, I have been stimulated to inquire whether the sarcomatous processes of the cord present any peculiarity in their history that would perhaps aid in future distinctions from tubercular processes. A comparison of twenty-six cases, collected from the literature of sarcoma of the spinal cord, with cases of massive tubercle of the cord, brings out a number of facts, some of them of practical interest. The clinical histories in many of the cases are imperfect, and care has been taken not to draw more positive conclusions than the facts at our disposal will permit. The following conclusions appear to be warranted by the facts:

1st. Sarcoma of the spinal cord occurs with about equal frequency in the two sexes. Of 26 cases 14 were in females, 12 in males.

2d. Sarcoma of the spinal cord is essentially a disease in adult life. Of 21 cases only 2 occurred before the twentieth year, at eighteen and sixteen; 5 occurred between twenty and thirty; 6 between thirty and forty; 6 between forty and fifty; 1 between fifty and sixty; 1 case occurred at seventy-one. Thus of the 21 cases 17 are found between the twentieth and fiftieth years.

Massive tubercle of the cord, on the contrary, is a disease of adolescent and early adult life, 15 of 24 cases having occurred between the fifteenth and thirty-fifth years, and 5 more before the fifth year. This fact may sometimes aid in diagnosis, for, other indications being balanced, sarcoma is much more probable than tubercle after thirty-five, while tubercle is much more probable than sarcoma before the twentieth year.

3d. **Etiological Factors** in the production of sarcoma of the spinal cord are practically unknown. In one case only does an injury, a fall upon the ice, appear to have exerted any influence; even here the influence may be questioned. In this case (Fischer) the sarcoma, which was of pial origin, extended almost the entire length of the cord. In the causation of tubercle, likewise, injury appeared to exert no effect.

It is of some interest to note that in three cases of sarcoma the first symptoms made their appearance during pregnancy. This occurred in the cases of Macalester, Glaser, and Attelmeyer. In a fourth case, that of Stavridis, symptoms of tumor came on during pregnancy, but the case cannot properly be admitted, as there was no autopsy. It is of course possible that the blood-state of pregnancy is favorable to the development of tumors of the connective-tissue type, but in thinking of the significance of the appearance in sarcoma during pregnancy it is well to bear in mind the possibility of mere coincidence, for sarcoma occurs at the period when a considerable proportion of women are pregnant.

4th. Most cases of sarcoma of the cord occur in the

dorsal region. The cervical region appears to be more often involved than the lumbar. In several cases the new growth extended nearly the entire length of the spinal cord.

5th. It is exceedingly difficult to obtain from literature the facts necessary to establish a full symptomatology. Results obtained in this way are usually labored, and the present instance would prove no exception to the rule. Certain facts, however, stand out clearly. In the first place, pain was the earliest and most prominent symptom of the process in about four-fifths of all the cases in which there is a reasonably full record of the symptoms. In a small minority of cases it appears that numbness or hyperæsthesia or weakness has preceded pain by a short period. The situation of the pain has, of course, varied with that of the new growth. When the tumor has begun in the cervical or lumbar enlargement the pain appears to have been referred especially to the corresponding extremity, though in some cases it was referred to some extent or chiefly to the vertebræ. Regarding the character and duration of the pain, the records are not sufficiently explicit to enable an opinion to be formed.

It may be assumed, however, with considerable confidence, that the pain was usually severe and prolonged, though intermittent. In solitary tubercle of the cord pain is an early and prominent symptom, but there is reason to think that it is ordinarily less severe and of shorter duration than in sarcoma.

Speaking generally, the early symptoms of sarcoma are mainly of an irritative and not of a destructive nature. This depends on the fact that the tumor commonly grows slowly from the pia, and produces symptoms that are chiefly meningeal at first, with little compression. Later the tumor involves the cord substance, and destruction takes the place of irritation. It is unnecessary here to dwell upon these symptoms, as they are well understood, and the study of these cases of sarcoma throws no new light upon them. If we compare the character of the symptoms in sarcoma with those of massive tubercle of the cord, we cannot fail to be struck with the much greater prominence of the destructive cord symptoms in this latter condition; a high degree of paralysis and anæsthesia is reached much earlier in the course of tubercle than in sarcoma.

And here we come to one of the most striking differences between the two conditions. In sarcoma the course of the disease is in general much slower than in tubercle. The cases of tubercle collected by Dr. C. A. Herter, in 1890, ran their course in a few months—usually about three months from their commencement. Of 20 cases of sarcoma of which the duration is given, 4 ran their course in less than one year, and of these, 2 are said to have lasted less than six months (1 about three months); 11 of the cases lasted from one to three years; and of the remaining 5 cases, 2 lasted six years, 1 thirteen years, 1 sixteen years, and 1 an unknown number of years. The average duration of the condition may therefore be set down as from one to three years.

It is hardly necessary to say that the symptoms were in almost every instance unilateral at first. This was true also of the cases of tubercle, but in the tubercular process the extension to the other side took place at a much earlier period.

In all of the cases from which the preceding conclusions have been drawn, the diagnosis was confirmed by autopsy. Cases of glioma of the cord have been excluded. Three cases were instances of fibro-sarcoma (Attelmeyer, Ledyard, and Bulteau), one was a central angio-sarcoma (Glaser) extending the length of the cord, in one there were multiple angio-sarcomata (Cramer), and in another case the tumor was an alveolar sarcoma.

It affords me pleasure to acknowledge my indebtedness to Dr. C. A. Herter, of New York, who has carefully gone over the case with me and rendered valuable assistance.

ABSCESS OF THE LARYNX.

By PRICE BROWN, M.D.,

TORONTO, CANADA.

Abscess of the larynx is generally acknowledged by authorities to be divided into perichondrial and idiopathic. The former is so well known in connection with specific and tubercular affections that nothing need be said of it at the present time, except to refer to one case, which, on account of its unusual character and abruptness of termination, renders it worthy of notice.

On July 14, 1892, I was summoned, in consultation, by Dr. Miller, to see a man, about fifty years of age, suffering from dyspnœa. Family history tuberculous. Three brothers were said to have died of consumption—two of them of consumption of the throat.

No history of specific disease. For years had been subject to sore-throat from colds. These would pass entirely away sometimes. In the latter half of June, while visiting, had slept in a damp bed. This was followed by acute laryngitis, from which he had not recovered. During the last week dyspnœa had been severe, but was not attended by marked dysphagia.

Examination. — Patient tall and spare, but fairly strong, and able to walk about freely. Inspiration long, difficult, and stertorous. Expiration shorter and easier. Voice not much affected, but harsh. Pharynx normal; but with the laryngoscope larynx proved to be œdematous, particularly the ventricular bands. They were pearly and translucent. Vocal cords almost hidden by the œdema. What slight parts could be seen were congested and infiltrated. The whole bathed in a light serо-purulent exudation.

Externally there was no swelling whatever, and no marked tenderness over the region of the larynx. On this single examination it was impossible to positively diagnose abscess. My own impression was, that it was a case of tuberculous œdema; but I was surprised at the complete absence of ulceration. The indications seemed to be either for scarification or tracheotomy; but as the impression, both of patient and friends, was that he was easier than in the early part of the day, I merely brushed the ventricular bands with a preparation of cocaine-menthol, leaving a spray to be used when required, with the understanding that I was to be summoned at any time if operation became necessary.

The following day, the 15th, his physician telephoned me that he was a little easier, and down-stairs most of the day. On the morning of the 16th a second telephone message announced that he was dead. The doctor had been hastily summoned. He obeyed the call immediately, but when he arrived the patient had expired.[1]

[1] Case reported, and pathological specimen exhibited, to Toronto Medical Society, October, 1892.

I assisted Dr. Miller in the post-mortem examination of the neck. There was neither external swelling nor discoloration. In dissecting the skin back from the thyroid and cricoid cartilages the scalpel accidentally cut into lower left margin of crico-thyroid membrane, followed immediately by exudation of yellow, odorless pus. After removal of the larynx the epiglottis proved to be free from œdema; while the supra-glottic portion was enormously œdematous, completely closing the cavity. This was lined with muco-pus, quite different, however, in color and consistency from the pus already mentioned. The color of these parts was of a translucent serous character. The trachea was without œdema, and free from pus. On cutting down the centre of the back of the larynx, severing the cricoid cartilage, the abscess was fully opened. It formed a cavity beneath the perichondrium of the front of the posterior and left half of the ring, extending partly to the right, but chiefly to the left, penetrating a little over the posterior surface of the left ala of thyroid, and down, as already noticed, to the cricothryoid membrane, completely raising without breaking the epithelial coating.

The patient undoubtedly died of apnœa from complete stenosis, produced by the pressure of the abscess beneath the vocal cords, and the œdema of the ventricular bands above.

Dr. Acheson kindly examined both the cartilage and the pus with the microscope, for tubercle bacilli, with an entirely negative result.

Idiopathic Abscess of the Larynx.—Of this second and rarer variety Richards, in the *International Journal of Medical Sciences* for 1890, records twenty-six collected cases, besides the thirteen previously reported by Sir Morell Mackenzie. In 1891 Irsay, of Buda-Pesth, reported one also; and Milligan, of Manchester, read an account of another, before the British Laryngological Association, in March, 1892. These forty-one cases are all of which I can find a distinct record.

The large majority have occurred between the ages of twenty and thirty years; and the frequency has been greater in males than females. In more than half the cases there was no definitely "known cause." In adults either cold or wet, or drinking cold water, has been supposed to be the chief factor; while in children infectious diseases has seemed to be the preponderating cause. In a large number of cases the abscess was small and well defined; but sometimes it involved the greater part of the larynx. Œdema, too, was a general concomitant, affecting to a marked degree the side of the larynx to which the abscess was confined.

With regard to position of the abscess: In six of Mackenzie's cases it was situated in the base of the epiglottis, in four in the ventricular bands, and in the remaining three in the ary-epiglottic folds. In Richards's cases the locality was more varied—six in base of epiglottis, six in subglottic region, three in ary-epiglottic folds, three in vocal cords, three in mucous surface of thyroid cartilage, two in arytenoids, two in pyriform sinus, and one in ventricular band. In Irsay's case it was situated in the left arytenoid, and in Milligan's, over the external surface of the right thyroid ala, and pointing internally to the laryngeal surface of right side of epiglottis.

Prognosis in children has been very unfavorable, and the same in adults where operation has not been accomplished. In children the death-rate with and without operation has been sixty-two and one-half per cent., or five out of eight. In Rilliet and Barthez's adult case death occurred before the abscess was fully formed. In Berger's, after two days' slight dyspnœa the symptoms became intense, and patient died the same evening. In Doring's, a soldier, complaining of slight pain in the throat, went on parade about noon, and died of laryngeal stenosis at 5 P.M. of the same day.

In treatment the necessity of opening is very marked, as out of ten cases reported by Richards as unopened nine died; while out of ten cases operated upon only one died. The imperative call for immediate use of the knife is also illustrated by the following case, which recently came under my observation:

W. H——, aged thirty-two, a bookkeeper, and enthusiastic la-crosse player, tall and athletic, spent the evening of June 27th at his club, arranging for a crack match to be played on July 1st. He felt quite well all evening and retired to bed about midnight. At 3 A.M. of the 28th he awoke with soreness of throat and difficulty of breathing. By daylight the symptoms had increased in severity, and a doctor was summoned. Not obtaining relief he was referred to me, and driven in a carriage to my office at noon, nine hours after the first symptoms of dyspnœa. At this time it was quite impossible for him to swallow. Breathing difficult and stertorous. Skin cool and clammy. There was no swelling of external neck, and only slight soreness on pressure. The pharynx was unaffected.

Examination with Laryngoscope.—Epiglottis very much swollen and red, completely hiding rest of larynx from view. In the centre of left side of laryngeal surface there was considerable bulging, and the mucous membrane was paler in hue. Patient said that at this point the pain originated. After applying cocaine, I at once opened it with the laryngeal lancet, and out of it oozed several drops of pus. As this diminished the size of the epiglottis very little, I dipped the lancet into carbolic acid and scarified the posterior surface from below upward in two places. Bleeding was quite free, and enabled a vision of the arytenoids and ary-epiglottic folds to be obtained. These were œdematous, more particularly the right ary-epiglottic fold. This was contrary to the general rule, being on the opposite side to the abscess. I ordered hot poultices to the neck, hot steam inhalations, and hot drinks if he could take them. 4 P.M.—Came to office by agreement, in close carriage. Pus still oozing from left side of epiglottis; swelling somewhat less. Right side still swollen and red. Right ary-epiglottic fold larger and more œdematous than on first treatment. After cocainizing, scarified it with laryngeal lancet. Patient had been able to swallow a little. Treatment continued. Ordered cathartic of cascara. 10 P.M.—Was again driven to office for treatment. Left side of epiglottis more natural in size. No pus oozing. Right side swelling much as before. Right ary-epiglottic fold almost filling the larynx. Lanced the latter more freely than the first time. Free discharge of serum and blood, but no pus. Did not lance the epiglottis. Poultices discontinued, but hot drinks and steam inhalations as before. Also ordered glycerine and iron mixture to be taken every two hours.

June 29th, 9 A.M.—Patient again drove over. Had passed a fair night. Had swallowed a glass and a half of hot milk. Œdema of right ary-epiglottic fold much less. Left side of epiglottis shrunken; but right side pointing and lighter in color. Lanced the latter freely, and with cotton probe pressed out several drops of pus. From this time improvement was rapid.

July 1st.—All discharge has ceased. Ary-epiglottic folds were normal, and epiglottis almost so.

July 3d.—Patient's last visit. Although feeling weak his throat feels well and he has a voracious appetite. A few days later he resumed his ordinary avocation.

In this case the lancings were done at four different sittings, each time affording marked relief to the dyspnœa. The lancets were sterilized before each insertion, and although the epiglottis discharged pus so freely, the swelling of the ary-epiglottic fold remained throughout only œdematous.

37 Carlton Street.

The Price of Opium is steadily rising in consequence of a diminution in the area of cultivation in Asia. It is thought that the price on the London market will soon reach five dollars a pound, an advance of about fifty per cent.

THE PREVENTION OF DEAFNESS.

By CHARLES A. BUCKLIN, A.M., M.D.,
NEW YORK.

This subject is worthy of attention because hearing is more frequently lost than any other of the special senses. If a general ignorance of the simplest principles of physics, as applied to the prevention of deafness, is, beyond dispute, the usual underlying cause of losing the hearing, then such an education on this subject as would enable the masses to recognize early the symptoms of approaching deafness, and the profession to appreciate the urgency of such symptoms, would be the way to prevent it.

Early recognition of the approaching ear disease and effective surgical treatment are the necessary factors for preventing incurable deafness. Very frequently the early symptoms of developing ear disease do attract attention and the family physician is consulted: the advice given at this period nearly always determines the fact whether the individual is to be deaf in the future or not.

The first warnings of the trouble are as follows: Frequently recurring colds in the head, annoying noises in the ears, an acute earache followed by a discharge which does not appear inclined to cease, thick voice, faulty articulation combined with mouth-breathing and annoying obstructions of the nostrils, all of these symptoms, if persistent, endanger the hearing and should receive serious consideration.

Patients annoyed by recently developed ear symptoms and seeking relief for the same occasionally meet men who are fully alive to the necessary surgical requirements; while at other times these patients encounter men who never make a complete examination, and who have a head-mirror, an ear speculum, a Politzer bag, and a galvano-cautery, and although they pose before the profession as specialists they only do for the patients what the most stupid people could do for themselves by applications of heat and repeated inflations of the middle ear. Then again these patients meet a "Don't-meddle-with-the-ear" class. If careful inquiry be instituted in this latitude it will be found that ninety per cent. of the inhabitants have had at some time of their lives some form of middle-ear disease.

A very large proportion of these cases can remember having had an acute earache, and give such a description as leaves no doubt of its having been an inflammation of the middle ear. Others do not remember such an attack, but upon inquiring of their family you will find someone who remembers all about it. Many will be encountered from whom no history of the attack can be obtained, still an examination of their ears demonstrates the previous existence of ear disease, although the hearing may be perfect at the present time.

If statistical evidence is to be accepted as the only standard in medicine, it naturally follows that no treatment is better than any treatment, because more cases get well without treatment. Hence the common statement, "Don't meddle with the ears." This statement has been further supported by certain means of treatment which have produced deafness in many cases that would have recovered if they had been left alone. For example, the use of the nasal douche; plugging the nostrils and allowing them to remain so for some time, which is a popular practice after a nasal operation; the introducing of the galvanic cautery and infected instruments into the nasopharynx; the ingenious idea of using bougies in the Eustachian tube; Adams's operation on the nasal septum, with the necessary subsequent treatment; prolonged, unskilled, and unnecessary manipulations in the nasopharynx—all these are means which, added to the statistical evidence above given, make the old doctors' motto, "Don't meddle with the ear," rather strong, but nevertheless dangerous.

This class of men have seen so many recover from ear trouble without treatment, or in spite of treatment, that they all live in a state of hopeful expectancy regarding their aural patients. But when the annoyance of the patient becomes unendurable and they at last consult some special man, he, as a rule, at this late date, can only inform them that organic structural changes have taken place in the ear and that the prospects are really very bad.

The unsatisfactory results obtained from special advice regarding ear disease of very long standing greatly discourage the profession from urging aural patients to seek relief.

It should be remembered that there is always a time when these incurable diseases of the middle ear are readily curable; but during this time these patients are usually waiting to see if they will not recover from natural causes.

Another very prominent cause why deafness is not prevented more universally is due to a want of thorough agreement among those who teach the profession regarding the treatment of diseases of the middle ear. Let them agree upon and teach a correct and uniform method of treatment for middle-ear diseases; teach the laity and the profession the necessity of giving threatening symptoms prompt attention and effective treatment, and the following generation will not be affected with deafness.

As the only diseases which play a very important part in producing deafness are those of the middle ear, and their direct and remote consequences, the following remarks will be confined to this one class.

The middle ear is practically one of the accessory sinuses of the nasal passages, subject to all the accidents which shut off the antrum, ethmoidal, sphenoidal, and frontal sinuses.

The symptoms arising from shutting off the middle ear are subject to great differences, owing to the fact that the cavity is closed from the external air by a simple drum-membrane and contains the mechanism necessary to transmit sound vibrations to a second cavity, containing the terminal filaments of the auditory nerve.

The conditions arising from the closing of this accessory sinus, called the middle ear, give rise to what is known as middle-ear disease.

The middle ear is without doubt more frequently shut off than any other accessory cavity of the nasal passages. This is due principally to the pneumatic conditions which exist alone in the middle ear.

It is absolutely necessary that the air shall at all times circulate freely from the nasal passages to the middle ears, otherwise the function of hearing is immediately compromised. The moment the air behind the drum becomes rarefied below the normal atmospheric pressure, to which the outside of the drum is constantly exposed, hearing is instantly greatly reduced.

Sucking the air from a toy drum and placing the finger instantly upon the vent destroys the musical tone of the drum as quickly and completely as rarefied air in the middle ear destroys the hearing.

The entrance of the Eustachian tube into a membrane which readily swells, and at a point sufficiently far back to be affected by all abnormal nasal conditions as well as efforts of swallowing, is a further cause which favors this sinus being so frequently shut off.

When the conditions are such that a constant partial vacuum in the middle ear is maintained, the vessels commence to congest because they are under less than normal atmospheric pressure. This is the starting-point of the disease which produces ninety-five per cent. of all the deafness in the world.

The suggestions as to the probable manner in which diseases of the middle ear most frequently start will be duly defended.

Diseases of the Middle Ear.—The eruption of essays, during the last twenty years, based each on a thousand cases, more or less, has been very prolific.

Each author appears to have demonstrated his peculiar conclusions to his own satisfaction, and yet there is no certainty or uniformity in the conclusions of any of them.

I have one of these essays before me which, while good, is a fair sample of the use that has been made of such sta-

tistical work in deciding how a congestion, inflammatory infiltration, or hypertrophy of the naso-pharyngeal mucous membrane produces middle-ear disease.

The statement is thus: "The development of the inflammations of the tympanum from nasal and pharyngeal affections has been explained in three ways. First, by the direct extension of the inflammatory process by continuity of tissue; second, from rarefaction of the air in the post-nasal space and tympanum during inspiration due to nasal stenosis; third, from obstruction of the mouths of the Eustachian tubes by adenoid vegetations. My own belief is, that it is always due to the first cause and never to the other two."

The fact that this essay is based on the personal observation of a thousand cases should, as in the case of all essays of its class, strengthen whatever logical conclusions the author arrives at. It is not probable, however, that the conclusions quoted above could be supported for ten minutes with the author himself as a jury.

Let us inquire. While the theory that inflammation extends from the membranes of the naso-pharynx to the cavity of the middle ear by continuity of tissue is a very plausible one, it is an exceedingly difficult one to demonstrate, because the following is what takes place previous to the time it is possible for the inflammation to extend.

A cold in the head causes the mucous membrane of the pharyngeal end of the Eustachian tube to become swollen. Rarefaction of the air in the naso-pharynx, the result of moderate obstruction to nasal respiration, frequently produces the congestion in the head, but it does not, as many authors state, rarefy the air in the middle ear. It simply places a condition similar to a valve in the Eustachian tube, which allows the air in the tympanum to be exhausted by efforts of swallowing and mastication without allowing the pressure to return when the exhausting power is inactive. If this condition always takes place before the inflammation can extend, and is sufficient to produce suppurative or non-suppurative inflammation of the middle ear, how is it possible to demonstrate the part that extension by continuity of tissue plays in the inflammatory process?

While suffering from an acute attack of rhinitis I have been, during the act of swallowing, gaping, or masticating, instantaneously seized with a loud roaring in the ear and great reduction of hearing. When inflating the ear the noise has ceased and the hearing has returned; within an hour the phenomenon was again observed, whereupon a spray of two per cent. of cocaine through the naso-pharynx, followed by inflation of the ears, caused the annoying symptoms to disappear permanently.

Had the rhinitis been due to causes which precluded its being relieved by such simple means, or from recovering in the usual time the average rhinitis, due to temporary causes, usually does, or had I been unable to overcome this congestion of the nasal cavities by any means, I certainly would have developed inflammatory disease of the middle ear, with defective hearing, and no one would have been able to demonstrate that my ear became inflamed by direct extension of the inflammatory disease from the pharynx.

It may, however, be shown that this trouble was developed without any extension of the inflammation to the middle ear, and as a direct result of reduced air-pressure in the tympanic cavity, because the hearing was perfect when the normal air-pressure was restored to the middle ear.

The majority take it for granted that many of the acute infectious diseases extend to the middle ear, and that this is the probable way in which the middle ear becomes affected. This is considered especially so in diphtheria. It certainly looks plausible, but even this form of extension of inflammation is difficult to demonstrate.

Some years ago, while passing through a serious attack of nasal diphtheria, I suddenly developed very severe pain in one ear, with inability to hear a watch except upon contact.

The hourly use of hot water in the ear during wakeful hours, continuous use of the hot water bag, very frequent disinfectant sprays through the nose, followed each time by inflation and rigorous constitutional treatment brought the acute inflammation of the middle ear to a recovery within seven days without suppuration and with perfect hearing.

I cannot imagine it possible that a truly diphtheritic inflammation of my middle ear had taken place, as I recovered so quickly and so perfectly, and without any suppuration. It must have been a very mild attack of simple inflammation of the middle ear.

Most of the middle-ear complications following diphtheria, that I have seen, have been suppurative. Occasionally the defective hearing resulting from diphtheria is the result of a paralysis, and sometimes proves permanent.

Those authors who do not believe that the pneumatic conditions of the middle-ear are so closely allied with the development of its diseases, but rather lean to the theory of extension by continuity of tissue, should also consider the following points:

Suppuration in the middle ear is more frequent than in all the other sinuses and cavities of the body taken together.

Why does not extension of inflammation by continuity of tissue produce suppuration as frequently in the antrum, frontal, ethmoidal, and sphenoidal sinuses? These diseases, as compared with suppurations of the middle ear, are rare.

It is impossible to avoid the necessary logical conclusion that the middle ear is an accessory sinus of the naso pharynx, which becomes frequently inflamed because it has an opening covered by a highly elastic drum-membrane that is exposed to the external air, thus making it the only sinus in which, when its opening is swollen, the air can be rarefied by swallowing, gaping, and mastication.

When a swollen condition of the mucous membrane, into which the Eustachian tubes enter, exists, they become so obstructed that the air exhausted cannot return to the middle ear, and a constant vacuum is consequently maintained therein.

We have no reason to believe that direct extension of inflammation to the middle ear takes place any more frequently than it does in any of the other accessory sinuses.

It is difficult to demonstrate that direct growths compress the opening of the Eustachian tube, but this undoubtedly happens. A fibroma or sarcoma favorably located will surely close the tube by direct pressure.

More extended observations will certainly bring to light some such cases.

Otologists as a class, for the past fifty years, have been disposed to treat the symptoms called middle-ear disease, rather than the causes, which are hyperæmia or hypertrophic conditions of the mucous membrane of the naso-pharynx, and tumors and deformities of the nasal passages.

They have had very good success in a fair proportion of cases, while in many others they have made flat and unnecessary failures.

As I think that the average specialist with equal experience has made no more mistakes in this direction than your humble servant, my readers will excuse me for speaking very pointedly of the many mistakes that are constantly being made.

A careful diagnosis, an intelligent prognosis, and great care not to overlook any existing complications are the three elementary factors for successful treatment of middle-ear diseases, as I will illustrate further on by clinical cases.

The routine practice for acute, subacute, and chronic non-suppurative disease of the middle ear is to employ forcible inflation, and wait for the rhinitis to subside, which it very often does. Attempts are also frequently made to reduce the rhinitis by the application of astrin-

gents to the naso-pharynx, which is also frequently successful. The number of cases, however, where neither of these methods can be successful are innumerable, and still the routine treatment is resorted to and persevered with in such cases.

Suppurative disease of the middle ear should be treated on the same general surgical principles that are employed in suppuration in other parts of the body.

Thorough cleansing and draining (which here also means forced inflation through the Eustachian tube) hot water through the external ears, disinfection, astringent solutions, and the rational consideration of any constitutional trouble, constitute the early requirements for treatment. When there are decided complications in the naso-pharynx the suppurative disease of the ear will usually be recurrent until these complications have been removed. The recurrence resulting from the exposure of the cavity of the middle ear direct to external atmospheric changes, as a result of extensive destruction of the drum-membrane, can be overcome by some simple form of protection, as cotton in the ear, when exposure makes it necessary. Recurrence from these causes is, however, over-estimated. Later sprouting granulations, called polypi, are to be removed. Symptoms indicating confined pus or dead bone in or about the middle ear should receive prompt attention, as they are very serious, and occasionally require active surgical treatment.

In all forms of middle-ear disease it appears that the cause of the congested pharynx is the first important element in deciding on the nature of the treatment.

The secondary connective-tissue changes, resulting from a long-continued inflammation in the middle ear, make very old cases amenable to no form of treatment.

At the present day there is certainly no excuse for following a routine line of treatment in diseases of the middle ear. With an intelligent examination, a rational prognosis can be given, and appropriate treatment selected at the start.

The following cases will illustrate some of the common mistakes which are being made constantly.

Case I.—Mrs. S—— came to me one afternoon with a child about two years of age, who had a profusely discharging ear. She said she was completely discouraged. The child had been some ten weeks under the care of one of the most prominent otologists, who had treated the ear just as I should have done had they come to me first, namely, inflating the ear, cleansing it, and insufflating boracic acid. I examined the nasal passages and pharynx, and I found nothing to tempt any rhinologist to operate.

I felt as discouraged about my prospects of giving satisfactory relief to the child as the mother did about my colleague's efforts.

I ordered the treatment energetically continued. The general anæmic condition of the child caused me to suppose that she was suffering from some acute infection. I therefore ordered moderate doses of quinine and iron. The difficulty entirely disappeared within a week.

This case illustrates a large class where inflammation of the pharynx is kept active by exposure to poisons from faulty plumbing and other malarial sources.

Case II.—An infant, three months of age, had always had great difficulty in nursing because it was unable to carry respiration on through the nose. The child had had a bad discharge from both ears since it was three weeks old. The usual routine treatment for suppurative disease was of but little assistance in controlling the discharge. After an examination I removed some adenoid granulations from the vault of the pharynx. The discharge was readily cured after this by the usual methods of cleansing and inflation.

I know this statement that adenoid vegetations are found so early in life is not generally supported by the weight of authority. I have, however, found them, and other observers will also demonstrate that they exist even at this early period. This is another class of cases that are commonly overlooked and go on to hopeless deafness.

Case III.—Mr. M——, a man very high in political circles in this city, had a suppurating ear nearly constantly for twenty years, and had been, to my knowledge, under the treatment of two of the best-known otologists in this city for a very long time without relief.

On one occasion, through the absence of his expert advisers, he fell by accident into the hands of a young colleague, who had had only five years' experience. He discovered a small mass of granulation tissue, which was touched with a little chromic acid on a probe. The patient was completely cured of a discharging ear of nearly twenty years' standing within a week.

This illustrates another class of cases where very expert and experienced men overlook very simple conditions that contribute toward the misfortunes of the afflicted.

The following case, which is instructive, has also fallen under my notice:

Case IV.—A child, five years of age, had crowded a bean into the ear. The family doctor, a thoroughly conscientious man, called a neighbor, who made a specialty of surgery, to remove the bean. Among the *débris* he exhibited, when he had finished the operation, was a large collection of clotted blood, pieces of the bean, the ear-drum and the ossicles of an ear which had never been diseased.

This serves to illustrate a certain class of self-confident ignorant men, who are sublimely unconscious of the things in the world which they do not know. Such cases are not isolated, and the only reason they are repeated is because they are not reported.

We have thus far considered cases with which the average intelligent man who observes closely and is careful will have good success.

We will next take up a class of diseases of the middle ear which cannot be relieved by the routine treatment, neither can the conditions in the nasal passages, which are their underlying cause, be overcome by producing cicatrices at desired points by caustics or electric cautery. To many men cases of this class are stumbling-blocks. They do not appear to use good judgment in selecting a proper means to overcome severe obstructive difficulties in the nose; neither do they appear to possess the necessary mechanical dexterity to obtain the desired results. Another misfortune is, they do not seem to know, even after operating a score of times, that they have in no way relieved the faulty conditions, and they do not appear to exhibit any intelligence in deciding when a properly selected operation can or can not be beneficial to the hearing.

Case I.—Miss F——, fourteen years of age, has had repeated attacks of suppurative disease of the right middle ear since early childhood. Has catarrhal deafness in the left ear without ever having been complicated by suppuration.

November, 1890.—Hearing under most favorable conditions of inflation: Right ear hears watch at one inch; left ear hears watch at three inches. Tuning-fork conduction heard, as usual in middle-ear disease, worst in best ear. The defects in her nasal passages and pharynx, which caused her deafness, were the most numerous and difficult to overcome I ever encountered. She had been operated upon innumerable times, principally by electric cautery and caustics, for the purpose of overcoming her nasal obstructions.

The entire adjacent surface of the right turbinated bone was adherent to the septum, as a result of denuding both mucous surfaces by senseless attempts to remove the nasal deformities with the electric cautery. There was also extensive hypertrophy of the left inferior turbinated bone. The naso-pharyngeal space was completely filled with an adenoid growth. Although the efforts for improving the hearing by inflation and the usual treatment had been almost continuous for about a year, still the hearing had grown steadily worse.

Prognosis.—The facts that these ears had not been im-

proved by most persistent treatment, and that the hearing was not improved temporarily in the slightest degree by inflation were discouraging. I could not demonstrate that the attempts at inflation were successful, consequently its failure did not count for so much in the prognosis. The fact that the tissues of the nasal passages were not in any sense atrophic, but, on the other hand, were extensively infiltrated with inflammatory products, led me to suspect that the accessory cavities of the middle ear were in a somewhat similar condition. This was further substantiated by inspecting the ear-drums. The ossicles could be seen shining through a more or less pink-colored drum, and they appeared of a bright red color. The patient could remember that during settled weather in the summer-time she had some days when her hearing was very much better than on others.

The above facts, with her youth, were the only points which seemed favorable.

Treatment.—In the right nostril it was necessary to overcome the deformities of the septum, resulting from an injury in early life, also all the deformity which was produced by no less than twenty operations with electric cautery and other ineffectual means. The lower turbinated bone from its firm cicatricial adhesion to the septum had been drawn entirely from its normal position. It ran obliquely across the nostril. Every time the periosteum of the turbinated bone had come thoroughly in contact with the cautery a periostitis had resulted, and the turbinated bone had become two or three times its original thickness.

With the author's universal saw I made the line of the septum a straight plane, by cutting from below upward, thus leaving the septal deformity fast to the turbinated bone. The saw was then placed under the entire length of the turbinated bone and it was amputated. The piece, when removed, contained the deformed turbinated bone, and the septal deformity firmly fastened together. The redundant tissue on the turbinated bone of the other nostril was removed with the author's universal snare. The patient having good control of her throat, I seized, through the pharynx, in two grasps, with the author's universal snare, the entire mass of the adenoid.

Results.—December, 1892. Right ear, which was formerly a discharging ear, heard the watch at twenty-five inches. Left ear promptly heard the watch at forty inches. No unpleasant symptoms about the ears, and the patient has never had inflammation of the middle ear in any form since the completion of the surgical treatment, which, owing to the annoying hemorrhage, required four sittings to complete. The results are permanent and remarkable. It will be remembered that before operation the best obtainable hearing was—right ear heard the watch at one inch, left ear heard the watch at three inches.

On the pure ground of experimental research I did not use inflation in the after-treatment of the ear trouble in the above case, because I feared my colleagues who do not indorse this line of thought might claim that it was difficult to settle what credit treatment by inflation was entitled to.

The sensible routine treatment for middle-ear disease should always follow the removal of abnormal conditions from the nasal passages, and although I dispensed with this treatment I advise others to use it.

Case II.—Miss C. B——, aged thirty-three, complains of having had defective hearing sufficient to annoy her in her daily vocation, and also troublesome roaring in the ears. Hearing under most favorable conditions of inflation: Right ear hears watch at two inches, left ear hears watch at four inches. Tuning-fork conduction intensified in right ear.

The patient had been previously operated on by the nasal saw, electric cautery, and chromic acid, which for some months caused the annoying symptoms to disappear.

The deformity of the septum had been sawed *at*, it had not been sufficiently removed to overcome nasal obstruction. The applications of electric cautery and chromic acid to the turbinated bones had relieved the nasal stenosis until the collateral circulation had become thoroughly re-established, when the trouble again returned. An adenoid complication in the vault of the pharynx had been entirely overlooked.

Prognosis.—The age of the patient was not, on general principles, favorable for a case of catarrhal deafness. The membranes were difficult to judge of. Examination of the middle ear showed that active congestion was still existing. Inflation did not improve the hearing, but she was quite positive that at times she heard much better than she did when the examination was made.

I was much more discouraged about the prognosis in this case than in the previous one.

Treatment.—In December, 1890, I removed the deformity of the septum with the nasal saw. Removed redundant tissue from turbinated bone of opposite nostril, and adenoid from vault of pharynx with the author's snare. The entire operation required three sittings, as the patient was very nervous.

Results.—Hearing, on April, 1891, twenty-four inches in both ears. Roaring in the ears, which had been annoying for nearly a year, had entirely disappeared. The same conditions continued in November, 1892.

Treatment by inflation after the operation was not used, for experimental reasons already mentioned, but I am sure that generally it would be better to use it.

Case III.—Miss H. W——, aged sixteen. Best hearing under every possible condition of inflation: Left ear hears watch at three inches, right ear hears it at six inches. Tuning-fork conduction intensified in the left ear. Had been under treatment by Politzer's method of inflation, applications of nitrate of silver to the posterior pharynx, and electric cautery and caustics to the hypertrophy on the turbinated bones, for about three months each year for six years. Any improvement obtained by this method had lasted only from a month to six weeks. Roaring in the ears was also a very annoying symptom.

Examination showed immense hypertrophy on both lower turbinated bones, very large pharyngeal tonsils, and a large adenoid in the vault of the pharynx. The prognosis was good because of age, plain causes existing for the trouble; atrophic processes had not become pronounced, the middle ear could be plainly demonstrated as being acutely congested, inflation did slightly improve the hearing, and the patient was positive that she had periods in the settled summer weather when she could hear much better.

Treatment.—Removed with the author's universal snare hypertrophies the size of a Lima bean from each lower turbinated bone, a large adenoid from the vault of the pharynx with the naso-pharyngeal tip of the same instrument, and both tonsils by a simultaneous tonsillotomy with an instrument in each hand.

Results.—The hearing commenced to improve within seven days. April 4, 1890, hears same watch in both ears at forty inches, tuning-fork conductions are equal, and roaring in ears has entirely ceased. The same conditions continue in December, 1892. For experimental reasons inflation was not used after the operation.

Case IV.—Mr. H——, aged thirty-six, experienced difficulty in hearing in both ears. His right ear had annoyed him with roaring sounds for three years, but he had short periods when the noises annoyed him very little. On March 9, 1890, when he applied for treatment, the right ear had been annoying him for six months, and he found it difficult to continue at his business, owing to his defective hearing. Under all conditions of inflation the right ear could only hear watch upon direct contact, left heard watch at three inches. Tuning-fork vibrations heard loudest in the right ear.

Examination showed extensive septal deformity, excessive redundant tissue on both lower turbinated bones, and a large adenoid in the vault of the pharynx.

Treatment.—The deformity of the septum was removed with the author's nasal saw, and the defects which were

not bone were removed with the author's universal snare.

Results.—May 9th, hears same watch at twenty inches, with both ears; noises have entirely disappeared, and tuning-fork is heard equally. The same condition continues in November, 1892. No treatment by inflation followed the operation.

The facts that the annoying roaring in the ears disappeared at certain states of inflation, or during very favorable weather in the summer months, are necessary factors in giving any encouragement in the prognosis regarding these annoying roaring sounds.

Case V.—Mr. A——, aged twenty-five, applied for relief from very defective hearing in July, 1889. He stated that he had started the study of dentistry, but had been forced to give it up, owing to his absolute inability to hear instruction. He had sought the advice of such specialists as had been recommended to him, and they had pursued the ordinary routine treatment for catarrhal deafness, but he grew steadily worse under it. Best hearing under all conditions of inflation: The right ear heard watch on contact, left ear heard it at one inch. Tuning-fork conduction was best in right ear. He was unable to carry on ordinary conversation.

The examination showed ear-drums sunken and ossicles appearing red through them, tinnitus annoyed him slightly. An extensive deformity of the septum was removed from the left nostril, which had completely obstructed respiration on that side. He had been subject to very frequent colds in the head, which he ceased having after the removal of the deformity of the septum.

It was fully four weeks before his hearing commenced to improve. In three months it had so improved that he could attend lectures with comfort and again resume his study of dentistry. He was the valedictorian of his class. Hearing: Right ear heard same watch at six inches, left ear heard watch at twelve inches.

I frequently find middle-ear disease the direct result of uncomplicated deformities of the nasal septum, but I cannot believe that before the age of twenty-five it is so constantly associated with diseases of the middle ear as are adenoids in the vault of the pharynx. I have seen a great many septal deformities, however, which were not associated with middle-ear disease, although they are certainly a frequent cause of this form of deafness.

Case VI.—This case illustrates that unfortunate class of cases which, when having defective hearing, wait too long before applying for assistance. Miss W——, aged twenty-three, had catarrhal inflammation of both middle ears of five years' standing. Tinnitus was not present. Heard watch in right ear at one inch, left ear at six inches. The appearances of the ear-drums indicated atrophic changes of the mucous membrane of the middle ears. The mucous membranes of the nasal passages were also atrophic. The patient stated that from early childhood she had been subject to very frequent colds in the head. These symptoms had, however, disappeared during the last two years, which is the case as the mucous membrane becomes atrophic. The pharyngeal vault showed the shrunken remains of an atrophic adenoid. Her voice was abnormally low, showing that its sounds were intensified to her. She is positive that her hearing is decidedly better in the presence of noise. The first symptom indicates that the sound vibrations reaching the internal ear are prevented from escaping as freely as they formerly had by inflammatory thickening, thus illustrating reflected sound like a railroad train passing through a tunnel. The improved hearing in a noise is owing to the fact that the joints of the ossicles are stiffened as the result of inflammatory action, and weak sound-waves are not sufficient to set them in motion; but when once set in motion by strong sound-waves any additional sounds are easily detected. Politzer has said that these symptoms belong to the most hopeless cases of middle-ear disease.

From my own observations this is not in all particulars true. I have seen such cases where the same symptoms showed before true atrophic changes had taken place, and I then found a very different condition of affairs. The hearing improved as a result of treatment, the voice was no longer intensified, and the peculiarity of hearing better in a noise entirely disappeared. But when the above peculiarities are observed in connection with atrophic changes in the middle ear, as in this case, the prognosis is hopeless. It is sad to observe this class of cases and know that it was only owing to the lack of a chance in time that caused these individuals to become hopelessly deaf. Case VI. illustrates the unfortunate side of the question, while Case VII. illustrates the fortunate side.

Case VII.—Miss G——, aged eighteen, had very large tonsils, a large adenoid in the vault of the pharynx, and also deviated septum. Had reduced voice and improved hearing when in a noise. She had suffered almost constantly from colds in the head since a child. She had had marked trouble with her hearing for five years. The deafness had become so profound that it prevented the girl from completing a contract of marriage. The parties were wealthy and the marriage in every way desirable.

All the authorities consulted concurred in the opinion that the case was hopeless. This prognosis, at the time, I thought, was beyond criticism. The left ear had suffered from repeated attacks of suppurative otitis media, which started up every time an acute cold was taken in the head. Hearing, April, 1891, under most favorable conditions of inflation: Right ear heard watch at one inch, left ear heard watch only upon contact.

Treatment.—Removed, on April, 1891, deformity of nasal septum, with author's nasal saw; removed adenoid with author's universal snare, leaving the tonsils, because I thought they could not contribute much to the defective hearing. The case did not progress favorably notwithstanding I tried inflation of the middle ear. In about a week I removed both tonsils. The patient claimed that she commenced to experience relief on the following day. Since the operative treatment the left ear has ceased to develop suppurative otitis media, which it formally did every few months.

Hearing, June, 1891: Right ear hears watch at fourteen inches, left ear at sixteen inches. Tinnitus, which was formerly severe in both ears, now only attracts slight attention in the right ear; it has entirely disappeared from the left ear. Tuning-fork conduction is increased in the left ear. The peculiarities of reduced voice and improved hearing in a noise have entirely disappeared. Conversation, which in April, 1891, could not be carried on with me, when sufficiently close to operate on the patient, was carried on readily in June, 1891, and the marriage contract was completed as a result of the improved hearing.

Since this and a few similar cases I have not been so sure about the part enlarged tonsils sometimes play in keeping up chronic rhinitis, which will be dangerous to the hearing. Surely no progress was made in this case until the tonsils were removed.

Each case I have cited simply illustrates a certain class, not one of which I ever succeeded in permanently benefiting by the usual routine treatment for diseases of the middle ear, which I practised with energy and perseverance at a much earlier date. I have given each case credit for the best hearing that could be obtained under the most favorable conditions of inflation before operating. After operating I have asked no favors of inflation in crediting them with the improvement in hearing. This certainly must be considered as fair by those who do not favor this line of thought.

There is another class of cases, which are frequently met with, which not only require skilled treatment but also great diplomacy in their management. The following is an example:

Mr. M——, aged forty-five, comes to me complaining of a sudden loss of hearing in his right ear. Examination showed an old chronic catarrhal disease of his right ear, which a moment's inspection demonstrated as incurable, and which must have existed for years. The examination of the other ear revealed a catarrhal otitis of

a much later date. Right ear hears watch on contact; left ear hears watch at four inches; hearing not improved in either ear by inflation. The patient insists that his entire difficulty arises from the defective hearing in his right ear alone. Every experienced observer would know that his right ear had not participated in hearing to any practical extent for years, and that the annoyance he experiences from defective hearing comes from the left ear being attacked with a similar disease, which would in time destroy the hearing of this ear as completely as it has that of the right ear.

Many of these patients, who are suspicious of everyone's opinion but their own, cannot be convinced that their complaint is entirely due to the last affected ear. Unless they can be convinced of their error it is much better to allow some other person to treat them, someone who can favor their views of the case. They are always ungrateful and unsatisfactory patients.

This case had an extensive deformity of the nasal septum, with obstructed nasal breathing, and constantly recurring colds in the head. The septal deformity was removed and the patient could breathe freely through the nose after the operation. The recurrent colds in the head have ceased, and sixty days later he heard the same watch with his left ear at twelve inches, an improvement of three hundred per cent. Still this man complained bitterly of the unsuccessfulness of the treatment because the right ear, about which he had been assured at the first visit there could be no improvement, had not improved.

This case illustrates a common freak of human nature, and a large class of difficulties one must meet.

It can no longer be disputed that the shutting off of that accessory sinus known as the middle ear, which contains the mechanical auditory apparatus, and which is subject to constantly varying pneumatic influences, is the greatest cause of deafness in the world. If our progeny are to avoid deafness, great care and attention must be given to the earliest symptoms which indicate that the sinus of the middle ear is not in normal communication with the throat, and adequate means must be employed to re-establish this connection when it has been interfered with. A simple swollen condition of the mucous membrane of the nasal passages is the common cause which produces defective hearing, through its effects on the ventilation of the middle ear.

The above trouble may result from an occupation which exposes one to a constant draught, as a desk directly under a ventilator, which is a more common cause than is generally supposed. Constitutional influences may also be the cause of chronic inflammations of the mucous membranes of the head that will not improve without intelligent medical treatment. This form of inflammations of the mucous membranes, when following acute infectious diseases, as scarlatina, diphtheria, measles, and all others of this kind will, in the majority of cases, when uncomplicated, recover in time to save the hearing without any direct or special treatment. It is well, however, to diligently inflate the ears while one is waiting for the inflammation of the mucous membrane of the pharynx to subside.

Surf-bathing always endangers the hearing by the direct injection of salt water into the middle ear from the nasal passages. The rougher the water the greater is the danger. Ear disease the result of this cause, if uncomplicated, generally recovers in a satisfactory manner under the ordinary routine treatment of inflation, and the patients frequently make a good recovery without treatment. Inflammations of the mucous membranes of the head, due to deformities, hypertrophies, and growths of the nasal passages, produce diseases of the middle ear which cannot be improved without surgical assistance. It is just this class of cases, that require operative assistance and do not get it in time, that make up the great mass of deaf people in the world.

It is surely true that the length of time which frequently elapses during which the unorganized products of an acute inflammation may exist as the prominent factor in causing deafness, is not generally appreciated. Only in proportion as the defective hearing is due to the unorganized products of an inflammation can any favorable prognosis be indulged in, and the earlier the stage of inflammation the more sure one can be that the products of the inflammation have not become organized into new tissue.

There is no help for that part of defective hearing which is due to true connective-tissue formations in or about the middle ear. The attempt is now being made to overcome some of the disastrous effects of contractions in the middle ear resulting from chronic inflammation, by removing the ossicles. I have not the courage to hope for any practical success from this method as a means of improving hearing. In a small proportion of cases it may relieve the annoying subjective noises in the head. I am, however, open to conviction and am anxious to see the hearing of old cases of catarrhal deafness benefited by any method. The man who can accomplish this end will be warmly greeted by mankind. The best that can be done up to this period is to cure the deafness before the products of inflammation have become organized, and that is a very wide step toward the welfare of the people.

To avoid disappointing both patient and surgeon, good judgment is necessary as to how much of the bad hearing is due to the early unorganized products of inflammation, and how much of the trouble is due to the late or organized products.

If we look at middle-ear disease from the point the cases cited indicate, we will not find otology so discouraging as it has been. We will benefit our patients, when we have a fair chance, where formerly flat failures were encountered, and reputations will be saved by refusing to treat those who cannot be benefited.

THE USE OF COCAINE TO PRODUCE ANÆSTHESIA OF THE SKIN AND TISSUES BENEATH IT.

By EDWARD JACKSON, A.M., M.D.,

PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC, SURGEON TO WILLS EYE HOSPITAL.

From the first use of cocaine as a local anæsthetic the difference between its effects on mucous membrane and on skin was universally recognized. The probable reason for the difference is the greater thickness and horny character of the epidermis, which offers a sufficient obstacle to prevent the rapid absorption of the drug into the sensitive tissues beneath. The magnitude of this obstacle varies with the thickness of the epidermis in different parts of the body, it being greatest on the back and outer sides of the extremities and least on the inner surfaces, and particularly on and near the eyelids.

Probably better local anæsthesia can be obtained in the skin of the lids by the external application of cocaine than in any other part of the body. The application, must, however, be sufficiently prolonged to allow of the soaking through of the epidermis by the fluid in which the drug is dissolved. While the various oils have been used to carry cocaine into contact with the tissue to be effected, probably because they do not give up the drug with sufficient rapidity to the serum of the tissues, they are of inferior value, and the watery solution gives better practical results. Its superiority, in my experience at least, has been very decided.

The Method of Applying.—Dropping the solution upon the surface is quite inefficient. In order to get the soaking of the epidermis necessary for the transmission of the drug, the surface must be kept moist for many minutes. This is readily accomplished by keeping it covered with a pledget of absorbent cotton, which is kept saturated with the solution.

The solution used should be as strong as possible, at least when it comes in contact with the tissue; if, how-

ever, the surrounding air is dry, and the absorbent cotton is freely exposed to the air, the evaporation will readily bring even the weaker solutions of cocaine up to near the point of saturation.

A most serious obstacle to the necessary soaking of the epidermis is the presence in it of a considerable amount of fat. This may be removed by carefully washing with soap or other alkaline preparations. Yet this very precaution has probably been the cause of complete failure in many of the attempts to produce cocaine anæsthesia of the skin. The presence in the epidermis or upon its surface of any residuum of alkali leads to the precipitation of the alkaloid cocaine from the solution of its salts in a form that is quite insoluble, so that profuse washing of the skin to remove the fat may by substituting the alkali render it far more impervious to the anæsthetic than it was originally.

In practice this may be guarded against by the prolonged use of pure water to remove all traces of alkali.

Again, the fat may be removed from the skin by careful washing with ether, and this is the best means if sufficient time is not available for rather prolonged preparatory treatment.

It is probable that the general condition of the lymph vessels materially influences the amount of the drug taken in through the epidermis. But to balance this, when absorption is most rapid into the skin, the removal of the drug from the point of introduction is also most rapid, so that the effect in anæsthesia obtained is not materially altered by the general condition of the lymphatics.

With the best application and under the most favorable circumstances the anæsthesia obtained by the application of cocaine to the surface is extremely superficial. Simply by such application continued while the incision is slowly carried down from layer to layer of tissue, the incision can be gradually and painlessly extended to any desired depth. At least this is true for incisions that do not present so great a surface as to cause danger of cocaine poisoning, and are not made through inflamed tissue. But this process is an extremely slow one.

If the incision is to be carried at one stroke below the true skin, even in the thinnest portions, the anæsthesia will not be deep enough to render it entirely painless, unless the cocaine is also introduced hypodermatically. To use it hypodermatically with the best success it is essential to introduce the drug into direct contact with the tissue to be cut or injured in the greatest degree of concentration practical, to get it promptly diffused throughout this tissue, and then to complete the operation before time has elapsed to allow of its being carried off into the general circulation.

The author's method, then, of using cocaine upon the skin is first to prepare the surface, either by washing with ether or with an alkali, followed by prolonged rinsing with pure water; then to keep the surface covered with absorbent cotton saturated with a strong solution of cocaine for from ten to twenty minutes. After that, for a rapid operation, to introduce the cocaine hypodermatically directly into the tissue to be cut, rapidly secure its sufficient diffusion by massage, and then perform the operation within a very few minutes. Used in this way, cocaine is capable of very greatly lessening or entirely preventing the pain of the removal of tarsal tumors and even of dermoid cysts, situated in the region of the lids or orbit. But it is always to be borne in mind that in the presence of hyperæmia and inflammation cocaine has little or no power as an anæsthetic.

The Determination of Sex.—Dr. A. C. Carney, of Dayton, O., sends the following as a contribution to the discussion upon the causes which may determine the sex of the child: "On March 1, 1892, in an examination of a young woman, I learned that her menstrual flow had just ceased. The following day she was married, and on December 4, 1892, she was delivered of a female child."

CONSERVATISM IN THERAPEUTICAL PROGRESS.

By R. ELLIS, M.D.,

DANBURY, CT.

In 1834 Bigelow published his discourse on "Self-limited Diseases," which was introduced in these words: "It is observable to many physicians that a change in the mode of regarding the treatment of disease has come over the medical world during the past quarter of a century. In certain cases a practice of watching, guiding, and trusting the salutary indications of nature has taken the place of the more acute interferences of art. Those men whose medical career began at a period antecedent to that which has been named will recollect that the course then most prevalent among the profession consisted in energetic and sometimes annoying and painful application of supposed remedies from the beginning to the end of diseases, whether those diseases were amenable to such treatment or totally incapable of being influenced by them."

Since these words were written fifty years have gone by, a half-century of medical progress. Slowly but surely the profession world-wide are adopting the belief that most diseases are self-limited and to day are treating symptoms alone in the majority of diseases, even though no self-limitation may exist. We know we are forced to do this because we do not know as yet what the causes of disease are. When we build our foundation in this direction, we may then discover the proper method of further development. At present, when we attempt to treat the cause of disease, we are like the person who attempted to construct a syllogism without a major premise—we have nothing to lean on.

Scientifically, no disease is self limited, because if we knew precisely the cause of a disease and its own peculiar remedy we could abort any disease in its infancy.

In our treatment of the cause of disease we have made little advance since Bigelow's time, save in one direction. We have the light of bacteriology attempting to clear up the dark mysteries of etiology, from which study it is hoped that pure specifics may be discovered.

We must confess that our growth in this direction is tedious, laborious, and slow. We know that germs and disease are present together, but we do not know as yet that they exist in all cases as cause and effect. A germ may be found in the bodies of several suffering from a similar disease, but we cannot in all cases state positively that the germ is absolutely the cause of such disease; we cannot assert that without the germ the disease is impossible.

The tubercle bacillus, even at this late day, is regarded by some more as a scavenger of the disease than as the direct and only cause, even though we know that the scavenger may by inoculation cause the disease.

Tuberculosis is a form of disease which may originate either from within or from without; if from within, the disease produces the germ as a necessary scavenger; if from without, the germ has been introduced into the body.

In no other way can we reconcile the fact that weak parents beget offspring who are tubercular from within at their very birth.

The abuse of the laws of breeding produces an inferior race who succumb easily from a variety of diseases; chief among these is consumption. We do not believe that this class from inherited predisposition all receive into their bodies the tubercle bacillus as the direct cause of their disease; some receive it, others develop it *de novo*.

As we advance in our knowledge of bacteriology more and more special germs appear, associated with special diseases, until in despair we cry out, *Cui bono?*

Our patients care little for germs or etiology or symptoms; they care only for treatment and prophylaxis. We fail to see that bacteriology has assisted us in their behalf, even though it has discovered the cholera bacillus, millions of which were swallowed without injury by a German scientist.

We are as much interested in the discovery of new germs as we are in the discovery of the new comet or the latest unearthed mastodon; they are interesting as facts, but they have no particular value to us as yet. We wish sincerely they did have.

The fault with us thus far is that we assume the science of bacteriology has proved more than it really has, and then we cry out, "Just see what we have proved," instead of hopefully saying, "Wait and see what we shall prove." Writers and teachers of "Practice," in their treatment of etiology have to "cram" in order to present that subject in the light of the most recent investigations. This must be revised and rewritten with each new edition.

The etiology of ten years ago is worthless if one wishes to be abreast of the times. Yet I do not believe that the authors of standard works on "Practice" believe that the etiology of to-day will be the same ten years from now. They insert under etiology the newest facts derived from the laboratory study of others, assume the absolute truth of their statements, and do not acknowledge that the etiology of disease is at present in the experimental stage, leading possibly to absolute truth.

We yearn for the Fabian policy of delay and expectation rather than for the policy of forcing a complete etiology from the facts up to date, which has and will produce much that is cumbrous unscientific chaff.

As busy, earnest practitioners we observe that of forty-three reported cases of ulcerative endocarditis the staphylococcus pyogenes albus was found twice, the pyogenes aureus fourteen times, the streptococcus pyogenes six times, the bacillus typhosus once, the diplococcus pneumoniæ six times, the tubercle bacillus once, and the bacillus fœtidus three times, with ten undetermined micro-organisms. We are glad this is true. It is interesting to read this in a practitioner's medical weekly. We believe it is scientifically all right, and try to make it of value to us in our daily rounds. We, however, are forced to ask, in one hundred cases how many undetermined and unclassified micro-organisms will appear? how many in one thousand?

In the treatment of skin diseases our authors persistently urge us to first seek the cause and then treat that. To help us they tell us that in eczema, up to date, we have fifty mucors, twenty varieties of penicillium, aspergilli, numerous cocci, bacilli, etc. The search is still going on. The more we discover the better pleased we seem to be, though we derive no practical benefit from such an infinitude of germs. We might here ask, if the discovered germs of eczema increase in the future in a like proportion to the past, how many thousand germs of eczema can be discovered in the next ten years? Who will classify them? Of what value will they be to us?

Erysipelas we now know is due to a parasite. We are forced to acknowledge, therefore, that all of our "specifics," from iodine to that beautiful preparation called "ichthyol," are of no value. We are glad the parasite has been discovered, and for the present we hope no more will be discovered. The parasite having been discovered, the burning question is, What parasiticidor can discover a parasiticidum?

It is granted to-day that Klebbs discovered the genuine diphtheria bacillus, and that Löffler first succeeded in developing pure cultures of the germ. We believe this to-day. Will the germ to-morrow be considered the cause of diphtheria or simply as an accompaniment in some cases of the pathological process? The great trouble with the investigations into the germ cause of disease is that there are too many too eager to find something. The result is the discoveries are given out almost before the eye has left the lens of the microscope.

We are beginning to realize that the science of bacteriology demands of her devotees all of their time; we are beginning to realize that her secrets are to be given grudgingly, and then only after incessant toil; we are beginning to realize that the discovery of a germ is but the opening of a new path which may or may not have at the end the coveted prize—a pure specific. How infinitely long these paths are is shown by the fact that thus far no one has completed the journey to the end of a single path, although hundreds of paths have been disclosed. The fact is each path is a tedious complicated labyrinth more intricate than those of old. If the end is ever discovered, it will be by the concentrated study of all upon some one labyrinth and not upon all.

We believe if the science of bacteriology is really to advance to a position of practical value, the necessity exists at present for deeper study and less newspaper talk. A national department of bacteriology should be established in every country; the foremost investigators should have charge of this department; their pay and status should serve as a stimulus for young men of ability in this direction to make themselves worthy of a position in this department; there should be a feeling of harmony among the departments of different countries; all should bend their energies not on discovering a million more germs, but upon discovering a specific for some known germ cause of disease.

If one parasiticide can be discovered, absolute and sure, the way to practical results will be clear. At present no beginning in this direction has been made. Then we shall by slow, tedious, careful investigation know what germs are the real causes of disease; what germs exist as companions to the causative germs; then we shall know the action of germs upon the body components and the action of the body components (especially the fluids) upon the germs; then we can believe what we read, for we will read only what has been positively proved, unless we care to read the journal devoted exclusively to the bacteriologist; then we, as members of a noble profession, will not again be humiliated by any such fizzle as was "tuberculin," so prematurely given to the world; then we shall not turn from the beaten path to try some new remedy which Dr. Eagertokill-germs believes will be of value. Our advance will be slower, but much more sure and satisfactory. As practising physicians we believe in the future of bacteriology: we believe it will prove to be of very great practical value, but we do not invest in any of the stock at present. We have been deceived and misled and feel that in the future we will not invest in any "boomed" stock. We purpose to be more conservative, for we lost all we invested in the tuberculin stock, which was "boomed" by so many of our best men. We desire to sink deeper in the old rut after this experience, especially when we remember the reports of those who declared that tuberculin would prove to be the greatest discovery of this century. We know now they were terribly mistaken, and we begin to realize how very difficult it is to be absolutely right, so we sadly leave the germ-workers to their researches and go back to the old path.

Here we have plenty to do in separating the chaff from the wheat. We know we heard our trusted professor some time ago say that the antipyretics were a great innovation and would prove to be of inestimable value; now he says, "Don't use them." We used to believe that the salicylates were almost specifics for rheumatic poison; now we are surprised to learn that they act as anæsthetics for rheumatic pain, but they have no action on the rheumatic poison. The therapeusis of diphtheria has been the Pharmacopœia from A to Z. Now thirty authors contribute their views upon the treatment of this disease, and we find about forty different remedies; did thirty more express their judgments, undoubtedly many other remedies would be suggested. The treatment in Germany differs from that in France, in France from that in England, in England from that in this country. It would seem after so much study that the best treatment could be agreed upon. Yet no two persons of authority in different countries will exactly or nearly agree: one clings to the old, another seizes eagerly all that is new, another takes a little of both, until even now our treatment of this horrible disease embraces as it did years ago the whole Pharmacopœia.

I ask, is it not possible for all to agree upon just what

remedies are of value in this disease? Take typhoid fever; the treatment to day varies from gun-shot prescriptions, from calomel and iodine, to absolutely no medicine.

In one of the largest of the New York hospitals a visiting physician, in the days of intestinal antisepsis, treated his typhoid cases with eight antiseptic remedies and published the brilliant results of his treatment. At the change of service another physician, equally well known, dropped all the antiseptics and limited the treatment to milk and lime-water, with equally brilliant results.

We dislike to confess that there is no direct treatment for internal pathological conditions and we therefore eagerly seize upon whatever is presented to us for trial, no matter where it comes from. Only yesterday a patient of mine gave her child, to cure whooping-cough, urinary sediment, because "her husband's mother gave it to her children." We act in just the same way. Dr. Jones, of Finktown, gave binoxide of manganese for amenorrhœa and reports the fact in the medical press. Soon many try it, and finally a leading gynecologist, without any reason for doing so, declares in his lecture that "he regards this new remedy almost as a specific in amenorrhœa." His students eagerly seize upon the statement, give the drug in their practice for a few years, with little or no success. When they read that Professor Toohasty no longer mentions the drug, his students correctly say that he never should have mentioned it. So it is with hundreds of remedies. We regard as useless to-day what we praised yesterday; we disown to morrow what we zealously adopt to-day.

It is distressing to think that this unscientific method of seeking for therapeutical advancement is likely to continue for a long time to come. When cholera recently visited some parts of the world, what was our treatment? Everything was suggested, no two treated the disease alike, and little scientific advance in cholera therapeusis was made, although Russia alone lost over two hundred thousand from the pest.

Though we believe in the future of bacteriology, up to date it has not lowered the death-rate. We find that just as many die, in spite of intestinal antisepsis, in spite of the science of bacteriology, in spite of the relations asserted to exist between bacilli and intestinal lesions.

Notwithstanding all this we are not discouraged. We know progress is slow and we know we are on a higher plane than we were in the past. These facts encourage us to renewed exertions.

The Pharmacopœia of the last century embraced, among other pleasant remedies, toads, frogs, virgin's slime, the dried flesh of a red-headed man dead from hanging, and other pleasant remedies. These have years ago entirely disappeared. We know that our Pharmacopœia becomes more and more progressive, and we are hopeful for the future, therefore, as we watch the steady advance of therapeutical knowledge.

Under the subject of "Treatment" writers of even five years ago threw in the whole Pharmacopœia, so as to be "thorough." The most recent practice drops much of the old, boldly and frankly states that we possess few specifics, and mentions under the treatment of each disease but a few drugs which are known to be of value as symptomatic remedies.

We gratefully and cheerfully take up this work on practice to relieve us from the dizziness and cerebral congestion produced by attempting to classify the names and therapeutical indications of the scores of new coal-tar derived "ins" which are daily being put upon the market, in the hope that the too credulous profession will take up their "new and important discovery" with the same zeal as was shown in the case of phenacetin, which up to date fulfils all therapeutical indications.

We are glad to note that this work does not invest much in coal tar stock. We believe their value is inflated by an overuse of printer's ink, and we propose to "fight shy" of too much of a good thing. We believe it advisable to be the "last to lay the old aside" and the first to receive the tested new.

Therefore we believe in asepsis and antisepsis; we believe that union without suppuration is the greatest surgical triumph of the century; we are proud of our surgical progress; we believe in "germs" and look upon the science of bacteriology with hope, not without fear; we cling to our old tested remedies and look askance and suspiciously upon the new, more especially the untested productions of the coal-tar series, appearing and still appearing; we believe in rest and massage and hydrotherapy and electricity; we believe in "tested" drugs, but not in gun-shot drugs any more than we believe in gun-shot prescriptions. We believe therapeutical progress should be influenced by a greater conservatism.

Clinical Department.

A CASE OF ABSCESS OF THE LIVER.[1]

By C. C. MOORE, M.D.,

PHILADELPHIA, PA.

S. D——, aged fifteen years, of good family history, but himself always a delicate child. History by parents: The patient from six years of age had frequent attacks of pain in the right flank in the region of the kidney and the liver. These attacks came at intervals of from four to twelve weeks and lasted from one to four days; recovery was by crisis and with a profuse discharge of very dark urine with a very thick sediment. These attacks were ushered in with extreme and sudden pain, suppression of urine, and usually followed excessive exercise or exposure, and were more frequent in warm than in cold weather. More time has elapsed between attacks, but they are getting more severe with the increasing age of the patient. He has been subject to no other disease, but his strength and endurance have not been equal to that of other boys. This is the history given by the parents, and, as he had always been attended by a physician of strange theory of disease, cause, and relief, no information could be obtained from former treatment. Each attack followed the other with exactly the same symptoms from beginning to recovery.

June 14, 1892.—I was called, and saw the patient for the first time. I found him suffering with pain in the right renal region, but extending all over the abdomen, with vomiting. There was no fever, but a pulse of 90 excited from vomiting. The tongue was coated, and there were all the symptoms of an acute gastro-intestinal inflammation, caused by abuse of the stomach with indigestible food. Thinking this was the trouble, I prescribed, and, comparing him to other patients, thought this would bring relief, and told the parents to call me if needed again.

June 15th.—I was called in the night, and found the patient with extreme pain in the usual position, suppression of urine, and all the symptoms of former trouble. I got a complete history of the former attacks, and, realizing that I had a difficult case to treat, I gave morphine hypodermically, and told the parents to send a sample of urine next passed, for examination. The urine was suppressed in both kidneys, while pain was only in the right renal region.

June 16th.—The urine examined was very dark, and blood settled thick in the bottle; reaction acid, and boiling showed about one-fourth albumin. He had slept well after the morphine, and was taking nourishment. The abdomen was flat and tense, the muscles were drawn in tonic spasms, and the movements of respiration were limited to about one-half as much as on left side. Pain was extreme over the region of the liver and kidney when percussing. The patient was turned on the right side with the knees drawn almost to the chin. Thinking to neutralize the acidity of the urine, a potash mixture was ordered with plenty of water to drink. The use of a potash mixture in acute inflammation of the kidneys may

[1] Read before the Northern Medical Society, of Philadelphia.

be questioned, but it did neither good nor harm in this case.

June 17th.—Bowels not acting, a bottle of citrate of magnesia was ordered.

June 18th.—Medicine acted, and patient looked better; urine apparently normal, but the pulse was 98 and temperature 99° F.

June 19th.—The fever and pulse were the same, but the pain was severe and increasing, and sufficient morphine was ordered for relief.

June 22d.—Had remained the same for four days. The bowels had moved every day, but began now to annoy him; so a forced enema was used, and a large scybalous mass was removed. I thought this would afford certain relief, but the temperature remained the same night and morning.

June 23d.—Temperature, 101° F.; pulse, 120; a typhoid condition existed. This continued for seven days. I used sufficient morphine to relieve the pain.

June 30th.—The intercostal spaces are bulging, and the area of percussion dulness extended to the fourth rib; the right lung was full of moist bubbling râles. He was expectorating a quantity of thin malodorous pus very like that from a pyothorax, and I chastised myself silently for overlooking a pleurisy and letting nature do the operating. He took food and drink, but was emaciating rapidly, and the discharge of pus through the lungs and mouth did not relieve pain, temperature, or pulse.

July 3d.—The strength is failing. I believed that an abscess had formed in the right side; but the problem was, whether it was of the kidney, liver, or lungs. The beginning was with the kidneys, then occurred the partial impaction of the bowels, then the bulging of the ribs and expectoration of pus.

July 4th.—John B. Deaves was called to assist; and, after about an hour's examination, we decided to find what was inside of the patient. Using ether carefully—for the heart was weak, and only one lung of any use—we explored the side with a small hypodermic needle. We found dark, thick blood over the liver and pus in the intercostal spaces above. I must say the pulse strengthened with the ether. I have often noticed that when the pulse is weak from absorption of pus it usually gains strength and continues strong while the ether is used, unless hemorrhage is profuse. The needle showed the presence of pus in the chest cavity, and, thinking to drain at the most dependent portion, an incision was made in the axillary line at the ninth intercostal space. The diaphragm was adherent to the pleura, and the puncture caused a free flow of very dark, thick blood. The ribs were fortunately not close to each other, leaving room for a thick gum drainage-tube, and the abscess cavity was washed with a bichloride solution, 1 to 2,000. No medicine was used, and from this time a rapid recovery followed. The wound was thoroughly washed every day, and the granulations gradually pushed the tube out in three weeks. There were no relapses of any kind. There was no jaundice at any time. When the wound closed, July 28th, the patient had his usual kidney trouble for three days. I now thought it time to interfere, and ordered a strong infusion of taraxacum lappa and absinthum.

August 14th.—Fourteen days after using this mixture the urine remained normal, when the boy had a profuse discharge of acid albuminous bloody urine; but there was no pain or complaint of feeling unwell in any way.

September 7th.—The urine had been examined every week, and had remained normal since August 11th. I can scarcely say how much good there was in the medicine used, but there has been no return of any urinary trouble up to this time, a period of nine months. This infusion was used at intervals for about four months.

In conclusion I must say there was no point to locate the abscess, and it was only found by several thrusts of the needle. There was considerable bending to the right side after the boy had risen from the bed: but this has been overcome by gymnastic exercise of the lungs and chest muscles, until expansion of the right lung is almost equal to that of the left. I believe the operation saved the patient's life, and, while it might have been done sooner, it was done earlier than in most of such cases. The temperature and pulse indicated pus on June 20th, and from that time to the establishment of drainage was fourteen days. Opening before adhesions of the liver to the diaphragm, and this to chest wall, had occurred to make a tract to drain through would not have been wise, and a delay of a day or two would, I believe, have destroyed life. In the two previous cases of liver abscesses, caused by injury, that I have seen, I believe the lives were sacrificed by delay of operation, depending on medicine that did no good whatever. Exploring with a hypodermic needle would have very easily diagnosed the cases. My patient could give no cause for this abscess, though about four months previous he had received a severe blow on the side with a base-ball; but this was not sufficient to cause him to cease playing. He had an attack of kidney trouble about two months after this accident.

November 9, 1892.—The patient has been perfectly well and is growing rapidly, still using the drugs before mentioned. If these medicines have any dominant physiological action it is on the kidneys: so I think it only just to give them some credit.

May 1, 1893.—The patient is well.

2349 Cumberland Street.

ACUTE IODISM.

By WILLIAM LOGIE RUSSELL, M.D.,

NEW YORK.

The following case is of interest because, so far as I am aware, no death from iodism has previously been reported.

The patient, a man sixty-eight years of age, was seen in consultation with Dr. William S. Moore. He was of robust physique, and enjoyed fair health with the exception of rheumatoid arthritis, with which he was affected. A slight exacerbation of this trouble had led him to call in a dispensary physician a few days before. The following was prescribed:

R.	Syrup. ferri iodid.	ʒ ij.
	Potass. iodid.	ʒ i.
	Syrup. simplicis ad.	ʒ iv.
M.	Sig.: ʒ j. t.i.d.	

One teaspoonful of this was given on the first day, two on the second, and two on the third. By this time the symptoms of iodism were so intense that the medicine was discontinued, and Dr. Moore sent for. A profuse coryza and conjunctival congestion were then present. So intense were these that hemorrhages occurred from the nostrils and eyelids. The skin had at this time a mottled hue, and bullæ were found on the face, scalp, neck, chest, arms, hands, legs, and feet. Some of the bullæ were as large as a silver dollar and contained sanious fluid. The eyelids ulcerated and became so swollen and covered with crusts as to conceal the eyeballs. The nostrils were completely blocked with crusts. The mucous membrane of the mouth and throat was inflamed and eroded, swallowing being painful and difficult. The voice became husky, and at last sank to a whisper and disappeared. Superficial ulcerations took the place of many of the bullæ. There were no gastro-enteric symptoms. The urine was not examined. The mind was clear, and there was no neuralgia.

The patient remained as described above for several days. He died on the tenth day from the administration of the first dose, from inanition and a low grade of pneumonia. There was no autopsy.

101 West Ninety-third Street.

The Pennsylvania Board of Health manages to exist on an annual appropriation of $6,000, but it evidently cannot do much sanitary work on this amount of money.

Progress of Medical Science.

Treatment of Pericarditis by Ice-bag.—In the *British Medical Journal* for February 18, 1893, is an abstract of an article by Dr. Leeds on this subject. He draws attention to the serious consequences, through damage to the cardiac muscle, of the formation of adhesions which too often result in pericarditis after apparent recovery. He pointed out that the present treatment of pericarditis was practically *nil*, or, worse than this, harmful, because very frequently the onset of this disease causes the physician to stop the use of the salicylates.

He has tried the application of the ice-bag over the pericardium in such cases with very good results. In his opinion it subdues the adjacent inflammation, relieves cardiac depression, and actually acts as a true cardiac tonic. Of course it should be used with caution, and the patient should not become chilled. The application is generally favored by the patient.

Is an Ectopic Testicle Worth Having?—Surgeons are divided in opinion as to the propriety of endeavoring to preserve testicles the descent whereof into the scrotum has necessitated operative interference. It has for years been assumed, though on what evidence we have no means of knowing, that undescended testes are not more useful than they are ornamental, and they have accordingly been remorselessly snipped off when, owing to the coexistence of a hernia, or inflammation of the retained organ, an operation has been thought necessary. The real reason why surgeons adopt this course is probably because it has hitherto been found impossible to secure the testicle in a comfortable position inside the scrotum, in spite of much ingenuity in, and variety of, procedure. Now that the problem of bringing down and retaining the testicle has been to some extent solved, the question of whether or not the game is worth the candle comes up afresh for discussion. It is pointed out that, after all, no accurate and reliable data have been obtained or are obtainable, in support of the theory of the functional worthlessness of the descended testicle. It is at most a matter of surmise, and the surmises ought to be in the other direction. Most patients, if consulted, would unhesitatingly prefer to have two testicles, provided no additional risk were involved, and their æsthetical love for symmetry ought, as far as possible, to be respected. Moreover, the absence of a testis might seriously impair the chances of a candidate for the public service, in the army especially, where the uniform is tacitly taken to imply a certificate of *testiculous habet*.—*Medical Press*.

Localization of Early Phthisis to the Apex of the Lung.—Dr. Campbell, in discussing the question as to why phthisis usually begins in the apices in man, says that the chief reason is that in him the extreme apex is extra-thoracic and not intra thoracic. It is therefore under exactly opposite conditions, as regards pressure, to the rest of the lung; in inspiration the intra-thoracic lung is under a pressure less than that of the atmosphere, but the apex is subject to the atmospheric pressure which is communicated to it by the soft parts covering it. This is forced downward into the thoracic cavity, with the result that it becomes slightly compressed, and air is forced out of it; this air meets the incoming air from the trachea and large bronchi, and the pressure becomes equalized. The result of this is that on inspiration only a small quantity of oxygenating air reaches the apex. Again, on expiration, the pressure in the apex being that of the atmosphere, and hence less than that of the rest of the lung, air rich in carbon dioxide but poor in oxygen is forced into it. From the above it follows that the contents of the apex are under most unfavorable conditions for becoming aërated, and thus the vitality of its tissues is lessened, and their resisting power lowered. Further, the same conditions which interfere with the elimination of carbon dioxide also operate to prevent secretions and excretions from finding their way out of the apices: and this retention, and the resulting decay and decomposition of waste products, must still further lessen the power of resistance of the tissues to the attack of bacilli. He is further convinced of the truth of his theory by the study of the anatomy of the chest of monkeys, in whom, owing to the length of the first rib, and more especially to the backward direction of the clavicle, the entrance to the thorax is so blocked that it is impossible for the apex of the lung to rise out of the thoracic cavity, and in whom, though phthisis is common, the apices are, as a rule, less affected. If this view be correct, it is evident that the contraction which takes place at the apex in phthisis is of the greatest value for the purpose of cure, for by its means the extra-thoracic portion may be drawn down so as eventually to become intra-thoracic. If it were possible to hasten this desirable result by excising the extreme apex, it is probable that in cases of early phthisis cure would take place far more frequently than it does at present.—*The Boston Medical and Surgical Journal*.

Scopolaminum Hydrochloricum: A New Mydriatic, and its Use in Ophthalmology.—According to Raehlmann (*Klinische Monatsblätter f. Augenheilkunde*, February, 1893), scopolamin is set forth by A. Schmidt, of Marburg, as an atropoid alkaloid from the roots of the Scopolia atropöides, and, like atropine, hyoscine, etc., belongs to the pharmacological group of the tropeine. As such, the instillation of its watery solution into the conjunctival cul-de sac causes dilatation of the pupil. According to Landenburg, scopolamin, as well as hyoscine, are contained in hyoscyamus without being identical with the latter. Its chemical combination differs from atropine, hyoscine, etc. It is rather isomeric with cocaine, but naturally yields quite different integral products.

The preparation was given to Raehlmann by Professor Kobert, with the information that, after experiments on the lower animals by internal administration, scopolamin had exhibited an opposite effect to atropine, that its influence on the cortex of the brain was not stimulating, like atropine, but paralyzant. It did not increase the action of the pulse, like atropine, but, on the contrary, retarded its action. These last-named qualities lead to the expectation *a priori* that the local special effects of the new remedy would be different, especially those on the conjunctival vessels.

Raehlmann has made use of scopolamin, both on the normal and the diseased eye, and reached the conclusion that, as a mydriatic and an antiphlogistic, it surpasses all other tropeines, including atropine. In strength of mydriatic effect, it resembles hyoscine closely. The remedy does not produce the disagreeable after-effects and double vision which, according to his experience, occurred from the use of hyoscine, but it possesses all the advantages which belong to hyoscine in comparison with atropine.

During the last half year he has employed the remedy in all cases in which atropine may be used, and has also used it by way of comparison with atropine, and has found that scopolamin is, in many cases, at least, equal to atropine, while in others it is entirely superior.

Hydrochlorate of scopolamin operates about five times as powerfully as atropine. It paralyzes, like the latter and in the same degree, the sphincter of the iris and the accommodation. The duration of the effect is ($\frac{1}{2}$ per cent., scopolamin compared with one per cent. atropine) about the same; perhaps somewhat shorter with scopolamin than with atropine. It is to be used in solutions of one to two *pro mille* ($\frac{1}{10}$ to $\frac{1}{5}$ per cent.), which solutions accordingly correspond in dose to $\frac{1}{2}$ and one per cent. solutions of atropine. Scopolamin operates best when used in divided doses. In a solution of two *pro mille* ($\frac{1}{5}$ per cent.), six or seven drops may be administered daily to an adult, or used every fifteen minutes during one and one-half hours. With children, correspondingly weaker solutions are to be used.—*Therapeutic Gazette*.

A New Symptom of Aortic Aneurism.—The signs and symptoms of aortic aneurism in its early stages are by no

means so numerous or so characteristic as to dispense with the need for any additional assistance that may be available. Some interest, therefore, attaches to Dr. Gilbart Smith's suggestion that one of the earliest symptoms in a certain proportion of these cases is hæmoptysis. He suggests that the existence of paroxysmal cough, associated with the expectoration of scanty bronchial mucus, tinged with blood, not to be accounted for by the existence of any concomitant disease of the lungs, heart, or kidneys, is often an indication of pressure on the lung by the sac of an aortic aneurism. What the value of this symptom may be in this relationship it is not at present possible to say. It must often be difficult to eliminate co-existent disease of the viscera. Pressure on the lung substance or on the air passages by an aneurism may determine symptoms indistinguishable from lung affections of other kinds, and it is conceivable that pressure from other causes, such, for example, as mediastinal tumors, might determine the same group of phenomena. The hospital physician who has his patients under close and methodical observation for long periods of time may be enabled to derive assistance from this symptom which is denied to the general practitioner, but if the symptom really possesses the importance which Dr. Smith thinks it merits, it is not the less worthy of attention, simply because it may not convey the same significance to all observers.

Lithopædion Removed by Laparotomy.—The Berlin correspondent of the *Medical Press*, writes that at a meeting of the Medical Society, Dr. Gottschalk showed a lithopædion removed by laparotomy, that had been carried by the mother for thirty years. The patient was a woman, aged fifty-four, who had married at twenty-one, and had a child at twenty-two. In the second year of her marriage she again became pregnant, and as she reached the term she sent for the doctor, who was not able to dilate the os uteri, in spite of violent pains. A diagnosis of extra-uterine gestation was arrived at, but in those days, when laparotomy was not so frequently performed as now, the patient was left to her fate. She was confined to bed for eighteen weeks with peritonitis, recovered, and again began to menstruate, but did not again become pregnant. As soon as she wore a binder that held up the child she ceased to have any trouble from it. Two years later the child sank lower down, with the head in the pelvis, so that difficulties in micturition came on. Her friends sought to procure her some relief by placing her on her head once a week, when the child fell away from the pelvis. Her troubles increased during the last summer, and she was finally sent to the speaker for operation. He found the pelvis completely filled by a tumor, and above it reached to the umbilicus. A tumor of bony hardness was felt with bony prominences. On operation the tumor was found covered with peritoneum, omentum, and intestines all grown together; these were separated, however, until the placental site was reached, which was on the left broad ligament and very vascular. The freely bleeding points were ligatured, when he found that the left Fallopian tube ran up quite to the pelvic ligament. The patient made a good recovery. Dr. Hahn said he had operated some years ago on a similar case. The patient then had carried the child thirty years. The muscular structures had retained their entirety, as shown by the microscope, and in the other parts also the organs were completely intact.

Bichromate of Potassium as an Expectorant.—In the *Brooklyn Medical Journal*, Dr. J. H. Hunt contributes an article upon the treatment of bronchitis and other conditions in which expectorants are needed, by the administration of bichromate of potassium. He recalls the fact that seventeen years ago Dr. Hutchins recommended to him the employment of one grain of bichromate of potassium triturated with nine grains of sugar of milk and mixed with twenty teaspoonfuls of water, as a remedy for severe suffocative bronchitis, occurring in young children. So extraordinary were the results produced that Dr. Hunt has constantly employed the drug since 1875. He states that the only article of importance which he has been able to find concerning it was one of Dr. Drysdale, of Cannes, France.

Dr. Drysdale believes that the bichromate of potassium has a specific action or elective affinity for certain organs and tissues, and that its action is most marked on the mucous membranes of the respiratory passages, nose, eyes, and mouth, and on that of the stomach and intestines; on the skin, liver, and kidneys, the fibrous tissues, periosteum, and bone.

Hunt's experience with the drug has been confined to diseases of the respiratory mucous tract. According to this author, it is best administered in a freshly prepared solution. The physician may readily carry it in the form of a triturate, which is readily dissolved in water at the bedside; or tablet triturates containing one fiftieth of a grain may be used. These triturates contain the minimum dose for a child one year old. Hunt claims that the bichromate of potassium is readily borne by the youngest infant, but that it should not be given within a few minutes of feeding with milk. To a child one year old he gives as much as one-twentieth of a grain to the dose, if oppression and suffocation are impending, and then diminished at one hour intervals. Drysdale says that no more than one-fourth grain should be given per day, but Hunt claims to have exceeded that amount without bad effects, instructing the attendants to diminish the dose if it acts like an emetic, but not to diminish the frequency of its administration. When it is rejected by the stomach it is without nausea or after-irritating effect. Dr. Hunt gives ten grains of the powdered triturate, or a corresponding number of one-fiftieth grain tablets, to be dissolved in twenty spoonfuls of water, with the best effect. This is probably due to the minute subdivision of the drug through trituration.—*Therapeutic Gazette*.

Typhoid Fever in Puerperal Women.—It has long been known that typhoid infection is rare in pregnancy, and that even when established is not rendered more serious by the puerperal condition. But, on the other hand, typhoid fever causes abortion or premature labor in about two-thirds of the cases, the more surely in the earlier months. This accident oftenest occurs from the third to the sixth month of pregnancy, and from the second to the third septenary of fever, though it is not unknown in convalescence. Although it is so generally admitted that this disease is not more than usually dangerous to pregnant women, prognosis becomes more unfavorable when it attacks the patient in the early period of lactation, though the cause of the difference is not well established. According to Carret, the affection under these circumstances is insidious, and may simulate septicæmia, when danger is usually great. Homolle thinks the puerperal condition renders the outlook more unfavorable, but neither of these authors assigns a reason for the special severity of typhoid fever in these cases. The gravity of the malady depends less upon complications than upon exaggerated symptoms, and may not these depend upon the modifications of the hepatic gland which occur during pregnancy, the normal functions of this organ and its lesions during infection by the Eberth bacillus? Siméby's researches showed that lactation is accompanied by fatty degeneration of the lobules of the liver. On the other hand, MM. Seredey-Legry observed a slight granular fatty condition of the periphery in typhoid fever. It would seem, then, rational to admit that the liver, thus weakened by lactation and the typhoid processes, is unable to play the part of protector from the poisons brought to it by the portal vein. These toxic products, with their generative microbes, exist in great quantities in the intestines during typhoid fever, and, as the system is thus deprived of a part of its defences, the patient very often succumbs. Here, as under other circumstances, according to M. Hunot, the prognosis of this disease depends upon the condition of the liver.—*Occidental Medical Times*.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, August 12, 1893.

PROGRESS OF THE CHOLERA.

IT is difficult to follow the progress of cholera in Europe, because of the policy of concealment maintained so persistently by the different governments. Every now and then we are startled by a report that the disease is epidemic in some unsuspected place, and a little investigation by disinterested foreigners reveals the fact that it has been raging there for weeks. The latest example of this is furnished by a report published in *The Lancet* to the effect that cholera has been epidemic in Marseilles for the last three months. The local officials, it is asserted, have carried their policy of deception to such lengths that even the Government has been led astray in regard to the real state of affairs. The Prefecture now admits that there have been six hundred and one deaths from cholera in Marseilles since the middle of May. On several days twenty deaths were recorded, and on one day two weeks ago the mortality went up to twenty-five. During the last four weeks there have been eight hundred and twenty-six deaths from cholera throughout France.

In Naples a veritable panic prevails, and it is said, though with what truth we do not know, that more than 100,000 residents, or one-fifth of the entire population, have fled from that city since the outbreak of the disease. The official reports greatly understate the facts. The report for one day recently said that there were nineteen new cases and nine deaths, but reliable private advices declare that there were fifty-two new cases and twenty-eight deaths on that day, and forty-nine new cases and twenty seven deaths on the following. Several cases of cholera are admitted to have occurred in Rome, and it is more than likely that the disease prevails there largely if it is not actually epidemic. This presumption is strengthened by the postponement of the International Medical Congress and by the report that the Italian Government has decided to forbid all pilgrimages to Rome while the disease continues.

The official returns on Sunday last announce that there were twenty new cases and thirteen deaths in Naples, and three cases and one death in Rome, during the forty-eight hours ending at noon of that day. It is safe to assume that the actual figures are considerably in excess of those given.

Dr. Young, of the Marine Hospital Service, stationed in Naples, reports that the sanitary regulations of the city are good and energetically enforced, and the water-supply is excellent, so that there should be no difficulty in checking an outbreak. The only thing in the way is the ignorance and superstition of the poorer classes. In spite of this, however, he says that the disease is spreading in the suburbs. The Italian authorities have finally consented to the adoption of measures for complete isolation for five days, of emigrants on board vessels before sailing for the United States. The pope has absolved the inhabitants of Italy from the obligation of fasting as long as the cholera prevails.

The accounts in other places are not reassuring. In Moscow there are between forty and fifty deaths a day from cholera, and the disease prevails to such an extent in South Russia, that the Government has issued an ukase closing all schools in that part of the empire. Twenty physicians have been sent to the Caucasus, fourteen to the Division of Kieff, and ten to that of Podolia. The disease is also marching westward from this part of Russia into Roumania and Galicia. Several cases have been reported from Lemberg, the capital of the latter province, and the disease has broken out at Brahilov and at Sulina, in the Pruth delta on the Black Sea, in the Roumanian garrison stationed there. A death from cholera in the east end of Berlin was reported on Sunday last, though the correctness of the diagnosis is doubted by the authorities. A bark from Cherbourg for Gravesend has arrived at the latter port with a case of cholera aboard.

In Alessandria, Italy, the cholera is officially declared to be extinct, and it is said that the disease is declining in Malta, the daily number of cases now not exceeding twelve.

The Karamania, an Anchor Line steamer from Naples, arrived in this port on August 3d, and was detained at Quarantine, owing to the fact that there had been three deaths on board from diarrhœal trouble, the last two on the morning of the day the vessel arrived. Since the arrival at Quarantine, two new cases of illness have occurred, which bacteriological examination has proved to be cholera.

A NEW DRUG HABIT.

WITH the putting forth of every new antipyretic is the statement that while it lowers temperature it does not depress the heart. Also in regard to each new hypnotic, it is stated that it induces quiet, refreshing slumber, and that there is no danger of the formation of the dreaded "drug habit" which so frequently results from the exhibition of this class of remedies. Paraldehyde, despite its intensely disagreeable odor and taste, has proven no exception to the general rule that "danger lurks in every (hypnotic) cup."

In the July number of the Edinburgh *Medical Journal*, Elkins gives an interesting account of a case of paraldehyde habit. It is probably the first of its kind on record. The patient was a married man, aged sixty-five, and a coachman by occupation. He was a man of naturally cheerful disposition, though liable to take offence easily. He had been troubled with insomnia for seven years, and twenty-six months before coming under observation (November, 1892) had begun to use, under medical advice, paraldehyde in small doses. The habit grew on him, so that on his own responsibility he had greatly increased the dose. When first seen he was using sixteen

ounces weekly. He had lost nearly thirty pounds, and had grown so weak that he had to lie in bed and be fed by his wife with a spoon. He had a slight rise of temperature every evening; a weak and irregular heart action, with palpitation; and a soft, intermitting pulse. There was considerable flatulency, bowels were costive, hunger excessive, and a paraldehyde odor was noticeable on the breath.

The symptoms referable to the nervous system are summarized by Elkins as follows:

1. Motor symptoms: General muscular weakness; general tremulousness, especially in tongue, facial muscles, and hands; gait feeble and unsteady; general restlessness. 2. Sensory symptoms: "Strange feelings" running through body. 3. Mental symptoms: Insomnia; great mental anxiety and agitation; discontent; unreasonableness; mental confusion; mental excitement; temporary loss of memory and incoherence of speech; shouting; tendency to strip himself; hallucinations of sight (he saw "strange beasts"); hallucinations of hearing (he heard his death would appear in to-morrow's paper, he heard his wife had said she wished he were dead); delusions (that he was being poisoned, that his milk was drugged with laudanum, that a woman was in his bed, preventing him from occupying it; that people were tormenting him, that the doctors meant to kill him, that the house was on fire, that harm was about to happen to him). It will be noticed that the hallucinations of sight and hearing and the delusions were all of an unpleasant kind.

Attention is also directed to the fact that many of the symptoms in this case are analogous to those found in alcoholics. This might be expected from the chemical relations of the two compounds.

The treatment was continued over a period of three months, and resulted in complete recovery. It was intended to diminish the drug gradually, but the patient's mental condition forbade any such arrangement being carried out. The first night he was allowed six drams of paraldehyde, the second night four drams. Thence all hypnotics were cut off till the eighth night, when fifteen grains of sulphonal were given. The latter remedy worked well, and was continued for some time in gradually decreasing doses. Thereafter the patient went on to gradual and perfect recovery.

The case is of much interest, both on account of its rarity and from its accentuation of the fact that no sleep-inducing drugs are entirely free from danger. In this particular instance it seems strange that any druggist would have been willing to dispense such a powerful remedy without distinct permission from a medical man. Such cases emphasize the fact that further legislation is needed in regard to the sale of poisonous remedies, and utter a warning to physicians to prescribe them with the utmost caution.

POSTPONEMENT OF THE ROME CONGRESS.

Much disappointment has been occasioned by the news, published in our columns last week, of the postponement of the International Medical Congress. Rumors of this postponement had been heard before, and therefore, although the source from which our information was derived was deemed trustworthy, we hoped the report might be premature, and that the meeting would yet be held on the appointed date. A later cablegram, to the Chairman of the American National Committee, from Professor Maragliano, of Genoa, the Secretary-General of the Congress, confirms our own previous report, however, and we can now announce definitely that the meeting will not be held until April of next year.

This will, of course, put an end to the Pan-American excursion to Rome which had been planned to take place by the Werra, sailing from New York on September 9th, and it may also prevent the attendance of some of the foreign delegates to the Washington Congress, who had proposed to be present at both meetings.

We fear, too, that the meeting next spring will be much less well attended than it would have been had it been held on the original date, for most of the universities will still be in session, and many of the more eminent medical teachers will be prevented by their professorial duties from going to Rome.

We may add that the postponement of the Congress throws a side light on the cholera in Italy, the presence of which in that peninsula the authorities have so strenuously endeavored to conceal. The occurrence of a few sporadic cases here and there would not have been of sufficient moment to cause so serious a step as this, and we are forced to the conclusion that Rome itself has been invaded by the scourge, despite the assertions of the Italian Government to the contrary. A further confirmation of this suspicion is furnished by the report that the Government is considering the advisability of forbidding for the present all Catholic pilgrimages to the Vatican.

MEDICAL MEN AS WITNESSES.

"A remarkable law concerning the examination of medical men as witnesses in negligence suits," says the New York *Sun*, "went into effect in this State at the beginning of July.

"It relates to the testimony of physicians or surgeons who are attached to any hospital, dispensary, or other charitable institution. Where such a man is required to testify in an action for the recovery of damages for personal injuries, in respect of information which he acquired in attending a patient at the particular institution to which he is attached, the new statute requires that the testimony shall be taken before a referee instead of being given in court before the judge and jury, as has always heretofore been the practice. However, the judge of the court in which the case is pending is empowered at any time, notwithstanding the fact that the deposition of the medical man was taken before a referee, to make an order requiring his examination upon the trial."

The *Sun* thinks that the law is "remarkable," and hints that it is unjust and uncalled for. Concerning this, however, we do not agree. There has been a great abuse of the subpœna power as regards hospital and dispensary physicians. The result was that these gentlemen were often kept a long time in court on petty cases, or called down for the bare chance of their testimony being utilized. Their regular work, which is at all times responsible and exacting, was thus seriously interfered with. Without committing ourselves to the exact details of the law, we feel assured that its general purpose is most wise, just, and necessary.

News of the Week.

Dr. F. A. Cox, of London, died of recurrent hæmoptysis on July 12th, at the age of thirty-seven years. He leaves a widow and four children. He was physician to the Western Skin Hospital and held several other appointments.

Dr. Jacques Bertillon, Chief of the Bureau of Vital Statistics of Paris, is in New York, and has been visiting the various bureaus of the Health Department here.

Three Patients are now under treatment for dog bites at the Pasteur Institute at Ninety-second Street and Central Park West, in this city.

Cholera Infantum is reported to be very prevalent among the Polish babies in Buffalo. It is supposed to be due to the practice of feeding the infants on stale milk. In the Polish district milk is kept as long as cream can be obtained from it, and the stale skim milk is then sold ice-cold at the rate of two quarts for five cents, and the stuff is fed to infants without being warmed, in order that it may not turn sour.

Dr. George C. Plummer, of Haverhill, Mass., was cruising in his yacht Matilda, with three friends, off Marblehead, on August 6th, when the craft capsized in a squall. The doctor was drowned, but the others were saved after clinging for an hour to the overturned boat.

A Medical University for Brooklyn.—The offer of $50,000 by Dr. C. N. Hoagland to the medical organizations of Brooklyn, on condition that they raise a like sum, for a building to serve as a general headquarters of medical men, has led up to a movement to organize a medical university. It is proposed to unite the Long Island College Hospital, the Hoagland Laboratory, the Brooklyn College of Pharmacy, and the various medical societies into one organization, to provide for advanced work in medicine, surgery, and pharmacy.

Another Blow to American Industries.—Notwithstanding the recent culinary efforts of a patriotic American to educate the German up to an appreciation of the savory and nutritious properties of Indian meal, Dr. Eugen Sell, of the Imperial Health Department, has reported to the Prussian Government that this substance is not a wholesome article of diet, and is unsuited for general consumption. If Dr. Sell could but examine some of our stalwart mountaineers in West Virginia and Kentucky, and see how they thrive on hog and hominy, he might be led to distrust the accuracy of his laboratory experiments.

Congress of American Physicians and Surgeons.—It has been decided to hold the Third Congress in Washington, D. C., during the last week in May, 1894. In place of the arrangement of former congresses, it has been determined that three afternoons and one evening of this meeting be given, in sessions of one and one-half hour each, to seven of the fourteen participating organizations; and that each society selected to perform this duty prepare its own programme for the period assigned it by the committee and select its own speakers. The selection of the societies to prepare programmes for the Third Congress was made alphabetically as follows: Anatomists, Climatologists, Dermatologists, Genito-Urinary, Gynecologists, Laryngologists, and Neurologists. The remaining constituent societies will be called upon under this rule to prepare programmes for the Fourth Congress in 1897.

An Investigation of Leprosy.—Dom Santon, a Benedictine monk, who has had a medical training, has been commissioned by the French Government to make a special study of leprosy in Scandinavia, Finland, Turkey, Asia Minor, Greece, and Egypt. When his investigations are complete, he will return to Paris, where he will lay his results before M. Pasteur, with a view to the possible discovery of a remedy for the disease.

The Quarantine Station at Brunswick, Ga., has been taken charge of by the Marine Hospital Service. This action is said to have been taken in consequence of the carelessness of the local authorities, which nearly caused an epidemic of yellow fever.

Dr. Ransel Mortimer Streeter died recently from heart failure, at his home, in this city. He was born in Chesterfield, N. H., March 23, 1839. He was a graduate of the University Medical College of this city, and began the practice of dentistry about twenty-five years ago. He was a member of the New York County Medical Society, the Odontological Society, and the Academy of Medicine.

Yellow Fever in Pensacola.—The Board of Health of Escambia County, Fla., reports that two persons have died from yellow fever in Pensacola.

Medical Society of Virginia.—The twenty-fourth annual session of the Society will be held in Charlottesville, Va., October 3–5, 1893. Authors must send to the Recording Secretary titles of papers at least five weeks before the session—failure in which will relegate any papers to the last day of the session. The Secretary classifies titles according to subjects, and assigns the order of their presentation. Half an hour only is allowed for the reading of a paper, and fifteen minutes for each discussion. The subject for general discussion is Chronic Nephritis; Leader, Dr. R. M. Slaughter, Theological Seminary, Va. Parties preparing papers on this, as also on other subjects, should inform the Secretary of any notes they may wish made in the Announcement, to be issued a month hence. Competitors for Dr. Hunter McGuire's prize of $100, for essay on "Obstruction to the Function of Micturition," as also for Dr. Joseph Price's prize of $100 for "History of Surgery and of Surgeons of Virginia," must forward their essays to the Recording Secretary on or before September 20, 1893. Applications for fellowship, with $2 initiation fee, should be sent to Dr. William D. Turner, Fergusson's Wharf, Isle of Wight County, Va. The Recording Secretary is Dr. Landon B. Edwards, Richmond, and the Corresponding Secretary Dr. J. F. Winn, Richmond, Va.

Iowa Public Health Association.—The third annual meeting of the Iowa Public Health Association will be held in the city of Davenport, Ia., August 31, and September 1, 1893. Headquarters will be at the Business Men's Association Rooms, in the Masonic Temple. A number of papers upon subjects of interest pertaining to sanitary science in its various branches have been prom-

ised. Dr. Paschal Davis, of Keokuk, is President, and Dr. P. J. Fullerton, of Raymond, Secretary.

American Dermatological Association.—The seventeenth annual meeting of this Association will be held at the Hotel Pfister, Milwaukee, Wis., September 5, 6, and 7, 1893. The following is the programme for the meeting: "President's Address," by Dr. George Henry Fox; "Antiseptic Treatment of Skin Diseases," by Dr. C. W. Cutler; "The Principles of Antisepsis in the Treatment of Eczema," by Dr. H. G. Klotz; "Cosmetics," by Dr. R. B. Morison; "A Case of Tuberculosis of the Skin Simulating Lupus Erythematosus," by Dr. W. A. Hardaway; "A Case of Rhinoscleroma," by Dr. G. T. Jackson; "Atrophia Maculosa Cutis, with a Case." by Dr. W. T. Corlett.

Report of Committee on Statistics. General discussion on: 1. Pityriasis rosea: *a*, its etiology; *b*, its relation to ringworm, seborrhœa, eczema, etc.; *c*, its treatment. 2. Dermatitis exfoliativa: *a*, its clinical forms; *b*, its etiology; *c*, its treatment. 3. "What do we understand by Pemphigus?" "Lupus Erythematosus as an Imitator," by Dr. H. R. Crocker, of London; "A Contribution to the Pathology of Acne Varioliformis," by Dr. J. A. Fordyce; "Angiokeratoma," by Dr. J. Zeisler; "A Paper, Subject to be Announced," by Dr. M. B. Hartzell. George T. Jackson, M.D., New York, *Secretary*.

The Late Dr. James O'Rorke.—At a special meeting of the Medical Board of St. Vincent's Hospital, held on August 1, 1893, to take action on the death of James O'Rorke, M.D., who, for nearly forty years, had diligently served as attending and consulting physician, the following preamble and resolutions were unanimously adopted:

Whereas, In the death of Dr. James O'Rorke, the sick in the hospital, the good Sisters, and the Medical Board have lost a faithful, devoted, and wise adviser, who, for more than half the allotted span of human life, had labored unceasingly, tenderly, and skilfully for the relief of thousands of sufferers, many of whom remember with gratitude his kind and gentle ministrations;

Resolved, That the members of the Medical Board signify their deep sorrow at the demise of their honored colleague, for whose integrity, sound judgment, and professional acquirements they have always entertained the greatest respect;

Resolved, That the Medical Board express to the family of the deceased its warmest sympathy in their sad bereavement;

Resolved, That a copy of these resolutions be transmitted to the family of the deceased;

Resolved, That this action of the Medical Board be published in the medical journals.

JOHN A. MCCREERY, M.D.,
Secretary of the Medical Board.

The Medical Treatment of Perityphlitis.—Revilliod claims to have had good success in the treatment of perityphlitis in the early stages by leeching, mercurial ointment containing belladonna, small blisters, calomel and opium, and gentle laxatives. Perfect quiet on the back is indispensable.

The Rôle of the Spleen in the Production of Immunity.—Tizzoni and Cattani have found that it is impossible to immunize guinea-pigs against tetanus if the spleen has previously been removed.

A Delicate Compliment to a Skilful Physician.—In a paper published in a recent volume of the *Archives des Sciences Biologiques*, Dr. Ouskoff, speaking of certain facts observed at the post-mortem table, says, naïvely enough: "Thanks to the presence in our hospital of so distinguished a clinician as the lamented S. P. Botkine, I have generally been able to continue at the autopsy the study of the complex symptoms observed during life." It must be a satisfaction to a distinguished clinician to be of assistance to his pathological colleague even if he cannot save his patients.

Dr. Henry Cropsey Cooper died recently, of cancer of the stomach, at his home in Woodridge, N. J. He was born in 1829, was a graduate of the College of the City of New York and of the College of Physicians and Surgeons, and served as a ship surgeon for several voyages on a sailing vessel between New York and Liverpool. He was a practising physician in this city when the Civil War broke out, and entered the Union army as captain in a company of the Seventh New Jersey Volunteers. He was wounded and was a prisoner for a time in Libby Prison.

The Life of Sir Morell Mackenzie.—Mr. H. R. Haweis writes to the *Tribune* of this city that the statement that he published a life of Sir Morell Mackenzie against the wishes of the family is incorrect. He says: "Just before the book appeared the family decided to suppress it. As the book was undertaken at their request, with material provided by them, and as the publishers had, with their full knowledge, printed and advertised for months, the publishers required their expenses paid. The family agreed to do so, and a sum was offered by them covering cost of publication and accepted. On May 29th I formally agreed to suppress the book, not on any terms proposed by me, but on the Mackenzies' own terms. They immediately withdrew their own offer, and refused to pay anything at all, leaving writer, publisher, and everybody out in the cold. The publishers then, without even consulting or informing me, issued the book. I am merely made the scapegoat, the Mackenzies being evidently afraid of the Empress's displeasure."

The Post-office Building in this city has been inspected by the Health authorities and has been found to be in a very unsanitary condition. There are two hundred and fifty-nine persons employed in the newspaper department in the cellar of the building, and there is an average of ten of them on the sick list daily. On the main floor, where the air is vitiated by the contaminated air of the cellar, there are seven hundred and forty-five employees. The building is under the control of the General Government, so that the Health Board can only make recommendations to improve the state of affairs. A copy of the report has been sent to Postmaster Dayton, and he has sent copies to the Secretary of the Treasury and to the Chief Supervising Architect at Washington.

Dr. James K. Davidson died recently at his home in Greencastle, Pa., aged eighty-three. He began the practice of medicine in 1833. He was a graduate of the Jefferson Medical College, Philadelphia.

Chicago Water is apparently not an ideal beverage, if we may trust the *Tribune* of that city. In an interview

with a citizen of Englewood, who has been examining the water microscopically, it says that "it is positively dangerous to drink unfiltered or unboiled water that is in as bad a condition as Chicago water is now in, and if cholera ever gets a hold in the city, with our sewage flowing into our water-supply as it does now, no one can tell what the devastation will be." Croton water is not æsthetically attractive, but it at least possesses the merit of being free from sewage contamination.

To Make a Better Job of the Next One.—To prevent a repetition of the bungling execution of murderer Taylor at Auburn, Warden Thayer, of Dannemora Prison, has been directed to put in an entirely new electric plant in his prison. The prison will be lighted by electricity, and the dynamo held in readiness should the regular apparatus fail to kill. It is hoped to have the new plant ready before the killing of murderer Foy during the week beginning August 27th.

The New York State Board of Health, at its meeting in Albany, on July 27th, elected Dr. Florence O'Donohue, of Syracuse, president.

Dr. John Rae died at his home, in London, on July 24th, after a prolonged illness. Dr. Rae was born in the Orkney Islands. He studied medicine at the University of Edinburgh, and after graduation there he took his degree as licentiate of the Royal College of Surgeons before he was twenty-three years of age. He served for a time as surgeon on a ship of the Hudson's Bay Company, and in 1845 accepted the command of an expedition to the Arctic seas to endeavor to complete the survey of about seven hundred miles of the coast forming the shores of a large bay, which Parry had failed to accomplish. This expedition, which proved successful, was the beginning of a series of voyages of discovery that made Dr. Rae famous as an Arctic explorer. He was a Fellow of the Royal Society, Fellow of the Royal Geographical Society, Honorary Correspondent of the Geographical Society of America, and Honorary Member of the National History Society of Montreal. The Founders' Gold Medal of the Royal Geographical Society was awarded to him several years ago.

Famine in China.—The inhabitants of the Province of Shan-Si, in China, are reported to be dying by the thousand every week of starvation, and the horrors of the situation are increased by cannibalism. Those who drop exhausted in the roads are attacked by companions, and the flesh of arms and thighs is hacked off and cooked or devoured raw.

King Otto, the insane ruler of Bavaria, is reported to be growing steadily worse, and it is believed that his death must occur soon.

A Novel Competition for Nurses.—In the course of the discussion on Nurses' Homes, which took place at the International Congress at Chicago, Dr. Billings, the President, expressed the view that it was about time that women manifested the latent power claimed for them in a practical and definite form. Architects and male experts had exhausted their ingenuity in designing nurses' homes, and he thought it would be well to invite the exhibition of woman's latent power by urging the superintendents of homes for nurses and training-schools to elaborate plans and enumerate each item which a model nurses' home and training-school should contain. The editor of *The Hospital* has adopted Dr. Billings's suggestion, and has decided to organize a competition which will be open to any woman engaged in nursing from any part of the civilized world. The following are the details of the proposed competition: Two prizes, namely, a first prize of $75 (£15) for the best plan sent in for competition, and a second prize of $25 (£5) are offered by the editor of *The Hospital*, London, England, for competition among lady superintendents, matrons, and nurses in the British Empire, the United States, and the countries of Europe. Competitors must send in the proposals in type-written form, which must consist of two parts: 1, A statement setting forth categorically all the rooms and accommodation which are necessary in order to make the proposed nurses' home a model of what such an establishment should be where room is provided for from fifty to one hundred nurses; 2, a second statement and plan prepared in similar form, which provides accommodation for from one hundred and fifty to two hundred nurses. Each of these specifications, 1 and 2, must be accompanied by plans drawn to a uniform scale, and must explain how the proposed home for nurses can be extended, should the growth of the establishment render such a step necessary.

Conditions.—1. The competitors must send their names and addresses by November 1, 1893, to Dr. J. S. Billings, U. S. A., Washington, D. C., and all plans and proposals presented for competition must reach Dr. Billings not later than January 1, 1894. 2. Dr. Billings, Dr. Henry M. Hurd, Superintendent of the Johns Hopkins Hospital, Baltimore, Md., and Miss Sophia S. Palmer, Superintendent of the Garfield Hospital, Washington, D. C., are appointed as the judges of the papers and plans submitted in this competition, and their decision will be final. Should the papers and plans submitted demand such a course, the judges reserve the right of withholding any award. 3. All proposals must be type-written on one side of the paper only, and all plans must be drawn to the uniform scale of one-eighth inch to one foot.

Special Note.—It is proposed to publish an account of the competition, with a selection from the competing plans, such publication to be undertaken by the Scientific Press (Limited), 428 Strand, London, W. C., at their option, to whom papers and plans will be sent by the judges after they have made their award.

The Relief of Symblepharon.—In the description of Dr. Rodman's ingenious device for the relief of symblepharon, in the MEDICAL RECORD of July 22d, it is stated that the pin is half an inch in length; it should have read one inch.

A Valuable Constituent of the Human Body.—A chemist computes that at the present market value the average human cadaver contains something like eighteen thousand dollars' worth of calcium. But, like the fabulous values of aluminum in clay, or of the gold in seawater, the cost of extraction at present prevents all profit to the would-be enterprising manufacturers, and the schools of anatomy will have no immediate cause for alarm as regards commercial competition.—*Medical News.*

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Nineteenth Annual Meeting, held at the West End Hotel, Long Branch, N. J., July 25, 26, and 27, 1893.

FIRST DAY, TUESDAY, JULY 25TH.

President's Address.—The President's Address was delivered by DR. HENRY M. LYMAN, of Chicago. After some reminiscent remarks relating to the study of nervous diseases he called attention to their predisposing causes, and said that we must not be content with the simple recognition of disease, but we must be able to classify it etiologically as well.

Rheumatism Affecting the Nervous System.—Such is the fact with regard to this condition. The marked forms chiefly affecting sensation are not so commonly recognized and are frequently ascribed to other causes. They are usually observed in elderly people of a nervous temperament and an arthritic diathesis, and differ from many other similar disorders of sensation in being transient, vagrant, and of brief duration. Among these ailments is a universal prickling over the surface of the skin; sometimes it is limited to certain points, where the patient experiences a sudden sharp prick, like a flea-bite. This may interfere with or delay sleep. Another disorder of cutaneous sensation often affects the scalp, and is occasioned by irritation of the superficial nerves of that region. The duration of the attack rarely exceeds a single day. Closely associated with these disorders are the various transient perversions of sensation that may be felt in the Eustachian tubes, the pharynx, and about the fauces. Another of the symptoms of masked rheumatism is a peculiar and disagreeable feeling in the tongue. This sometimes assumes the severity of a genuine neuralgia, and manifests a greater degree of persistence when associated with obesity, diabetes, or gout, than when connected with rheumatism alone. The œsophagus and fauces and sometimes the muscles of the eyeballs are similarly affected. These patients are also attacked by a paroxysmal cough associated with headache. The most distressing of all these forms of pain is gastralgia. The previous history and the concurrence of other rheumatic symptoms of a more stable character will, of course, add greatly to the certainty of the diagnosis.

Heterogeneous Personality.—DR. SMITH BAKER, of Utica, read a paper with this title. He defined heterogeneous personality as that condition in which the characteristics of ancestry are not blended into a permanent whole, and reported the case of a little girl who presented frequently recurrent attacks of functional perversions and distress which could not be satisfactorily explained except upon the inference that the dissimilar traits noticeable in her grandparents had not been blended in the personality of her mother, and so had proved to be the ground-field of the grandchild's affection. But the question arises, Is such a view of the case professional or scientific good sense?

We can never answer intelligently until the commoner facts of family life shall have been more minutely studied. Thus, such trite matters as dreams, somnambulism, the solving of problems unconsciously or subconsciously, the up-rush of facts and arguments in the act of composition, and the play of genius, should be investigated.

Inquiries in states of acute illness, and the study of moods and transformations of character, etc., all should receive more attention by physicians in order that causation in cases of functional derangement may be the more accurately conceived. In doing this, assistance may be found in many instances of so-called reflex disease. Heterogeneous personality should always be looked for in the neuropathic constitution. But more particularly is this of use in considering the problems presented by neurasthenia and the sexual perversions. Not so frequently perhaps is the trouble owing to the commonly assumed overwork, etc., as to the unceasing warfare within between the "lower" impulse and the "higher" determination. Students, professional men, and many others whose physical abnormities or mental peculiarities reveal the sensitive, easily impressed nature, are especially apt to be victims of the uncoalesced personality. Its bearing upon questions of marriage and parentage renders it worthy the attention of all.

DR. LYONS, of New York, referred to the opposite sides of character as seen among the insane. An educated woman may be agreeable and lovable in her normal condition, but vicious when in the abnormal state. He knew of such a patient who would frequently apologize and do her utmost to resist the impulses to do wrong. He thought that such behavior might be due to abnormity in the development of the cerebral hemispheres or to some interference with the circulation.

DR. PARSONS, of Sing Sing, expressed the view that in persons with a tendency to evil thinking and acting, such might be overcome by suitable environment. After a time the absence of restraint permits of a continuance or permanency of the abnormal condition. This would probably account for many of these cases.

DR. HINSDALE, of Philadelphia, spoke of two authenticated cases of double-consciousness. He thought that the medico-legal features of such cases, as well as those of changes in personality, were of special interest and should be reported and carefully analyzed.

DR. SEGUIN, of New York, believed that atavism was the more rational explanation. Blending of the characteristics of ancestors occurs normally. It was not right to confuse double-consciousness of an epileptic nature with conflicts of character and personality.

DR. J. J. PUTNAM, of Boston, said that the treatment rested upon the systematic development of character. Hypnotism has taught us much in regard to this condition, and brings out in a striking manner certain phases of character. He recommended the development of the inhibitory powers.

DR. F. X. DERCUM, of Philadelphia, thought the case reported by Dr. Baker recalled the fact that there was lowered vitality at certain epochs in women. Relationship between states of health might account for the peculiar mental variations.

DR. BAKER, in closing the discussion, referred to the various definitions of personality as being not sufficiently inclusive of the facts to be of accurate use. He urged the importance of the study of the subject, especially in its bearing not only upon the causation of actual disease but in its relation to all our educational ideas and practices as found to-day in our school system. In this way we find means of obviating detrimental traits, and also of making dominant those more desirable and healthful.

Detention Hospitals for the Insane.—DR. MATTHEW D. FIELD, of New York, read this paper. After speaking of the wrongs inflicted upon the insane by committing them to county jails and prisons, there to mingle with tramps while awaiting the appointing of physicians to pronounce upon their mental condition, he gave a description of the Reception Pavilion for the Insane at Bellevue Hospital, and the methods of examination and commitment by the city examiners. He declared the pavilion to be in every respect a hospital, with resident physicians and competent trained attendants. Though a plain and inexpensive building, it served its purpose very well. He advocated the establishment in all large cities of similar hospitals for the reception of those suspected of lunacy. He said that an ideal institution for this purpose would be a hospital constructed on the pavilion plan for the reception of the insane, inebriate, and neurotic, with a small amphitheatre and sufficient wards for proper classification and detention for a reasonable time. A competent visiting, resident, and examining staff of medical officers should be chosen, and clinical instruction regularly given. Such a hospital would secure prompt, humane, and scientific treatment. The opportunity for longer observation, securing histories and examinations, would

result in more complete and accurate certification. There being no need for hasty transfer to other institutions, the feeble, sick, and certain selected cases could be detained for treatment, and clinical instruction would be easily accessible to the entire medical profession.

Dr. Knapp, of Boston, said that there are no detention hospitals in Boston, and they have felt no urgent need for them under existing Massachusetts laws. A few emergency cases requiring immediate restraint are admitted to the general hospitals. Otherwise they can be taken at once to the nearest asylum on emergency certificates. These consist of two separate certificates. A bond must be given by the superintendent or one of the physicians to the effect that the patient is to be formally committed or released within five days. This system has proved eminently satisfactory and has rarely been abused.

Dr. Mills, of Philadelphia, stated that the method described by Dr. Field was in vogue at the Philadelphia Hospital. There was a detention ward for isolating cases of insanity. Two physicians are assigned to examine these patients before commitment. This ward has also been used for several years for clinical instruction.

Dr. Preston, of Baltimore, remarked that their lunacy laws were inadequate. They are endeavoring to establish a detention ward. At present insane patients are kept at police stations, as no general hospital is prepared to receive them. Their method of dealing with such cases is entirely unsatisfactory.

Dr. Parsons agreed with Dr. Field, and believed that such a ward would serve to diminish the number of improper cases sent to asylums.

Dr. Baker thought that a detention ward would prove extremely valuable for suspected cases of insanity as found in private practice.

The President said that in Chicago they have such a ward in the City Hospital where these cases are detained until transferred. Their commitment laws are now quite satisfactory.

The Temperature in General Paralysis of the Insane.—Dr. Frederick Peterson, of New York, read a paper with this title. He first reviewed the literature of the subject, calling attention to the statements of the various authorities that there are in general paresis extraordinary daily variations of temperature, that the average bodily temperatures are subnormal or hyperpyrexic, and that axillary asymmetry of temperature is particularly frequent. With the assistance of Dr. Langdon the temperature of twenty-five cases from the wards of the Hudson River State Hospital for the Insane was carefully studied. Observations were made every two hours for one week in each case, and in ten cases temperatures were taken in the two axillæ simultaneously every two to four hours for a week. He had reached the following conclusions:

1. As regards the average bodily temperature, it corresponded with physiological norms. The statements in literature as to hyperpyrexic or subnormal averages could not be sustained.

2. The diurnal oscillations of temperature in paretics also correspond to physiological norms. Observations found in literature as to frequent extraordinary daily variations in such cases seemed to be absolutely erroneous.

3. Asymmetrical axillary differences were so small that they could not be considered as abnormal, and certainly not of any diagnostic significance.

4. When unusual variations of temperature occur in general paretics, their cause must be sought for in conditions not related to the pathological phenomena of paralytic dementia, but depending upon other thermogenic features unrecognized by the physician, or "masked" by the mental state of the patient. Thus in Case 2 of his series an increasing hyperpyrexia was noted during the second week's observations, but the pneumonia causing it was "masked" until the fifth or sixth day, the patient dying on the sixth day. Again, in Case 10, where the highest single daily oscillation was 3.4°, and the average daily oscillations for the week 2.2° F., the patient had bed-sores on the sacrum and heels, and was undoubtedly somewhat septicæmic. That the temperature might vary in the paralytic seizures of these cases was not gainsaid, no observations having been taken in such conditions.

Dr. Gray, of New York, said that a large number of different pathological conditions are often included under the name of general paresis. He thought a number represent the terminal stages of intra-cranial syphilis.

Dr. Isaac Ott, of Easton, Pa., did not believe that the heat centres could be located from the symptoms of general paresis.

Dr. J. J. Putnam mentioned that he had occasionally noted oscillations of temperature in paretics.

Dr. B. Sachs, of New York, agreed with Dr. Gray as to the question of diagnosis. The results of his observations coincided with those of Dr. Peterson. He had recorded the rectal temperature. Elevations were often due to complications from gastric disturbances. The temperature was usually a little higher than in those who had no organic disease. He inquired if clinical studies of the heat-centres had ever been made.

Dr. Ott, in reply, said that he knew of only two cases of pistol-shot injury to the brain associated with immediate rise of temperature.

Dr. Parsons remarked that in one of his cases the temperature was always normal.

Dr. Charles K. Mills, of Philadelphia, regarded the manifestations of general paresis as so diverse in character that we can thus account for the different experiences of various observers.

The Anatomical Changes in the Spinal Cord in an Old Case of Infantile Paralysis.—Dr. Joseph Collins, of New York, presented numerous sections of the spinal cord and reported the history of a case of infantile paralysis of long standing.

Progressive Muscular Atrophy.—Dr. G. M. Hammond, of New York, exhibited microscopical specimens and gave the pathological report of two cases of progressive muscular atrophy, and referred to the fact that considerable confusion is occasioned by the misapplication of the term "peroneal type" to a disease totally dissimilar to the one under consideration.

The first patient was a woman, forty-six years of age, without history of gout, rheumatism, or syphilis. In the fall of 1889 she stumbled over a chair, bruising the right shin slightly, and a few days afterward she was unable to walk as well as formerly. Soon after, there was marked weakness of the flexors of the foot and the extensors of the toes. By October, 1890, there was complete paralysis of the entire right leg, with reaction of degeneration, loss of power and electrical contractility of the anterior tibial muscles of the left leg, and atrophy and loss of power of the thenar and hypothenar muscles of the right hand. Gradually but rapidly the other extremities became involved, and ultimately the abdominal and intercostal muscles were affected. She died suddenly, from either cardiac or respiratory paralysis.

The sections of the cord showed sclerosis of the pyramidal tracts and atrophy of cells in the anterior horns, and degeneration of Gower's column throughout its entire extent. The conclusion to be drawn from the clinico-pathological study of this case would be that the muscles of the hand were supplied by the mesial group, and the muscles of the forearm from the anterior group of cells in the anterior horn.

In the second case, seen in 1882, the disease only affected the muscles of the left thumb. He had the opportunity to watch the case to its termination in 1893. It ran the usual course and was in every way typical. At the time of death all of the muscles, from the level of the armpits upward, except the facial muscles, were atrophied, as well as those of the upper extremities. She became maniacal and finally died from exhaustion. The cord and medulla were examined and the changes were identical with those described in the preceding case. He concluded that these cases demonstrate that progressive muscular atrophy is due

to a degeneration of the cells in the anterior gray masses and the antero-lateral white columns. Also, that it is superfluous to divide progressive muscular atrophy into different types, because the disease does not invariably begin in the same group of muscles.

The last two papers were discussed together.

Dr. Mills agreed with Dr. Collins's views as to the arrangement of cells presiding over the flexors and extensors. He suggested examination of the nerve-roots at the extreme limit of the lesions.

Dr. Sachs thought such a careful pathological study will ultimately lead to better results than the usual clinical methods. That the Aran-Duchenne type was of spinal origin there could be no doubt, but he was not certain that the case of Dr. Hammond represented the peroneal form of progressive muscular atrophy as described by Charcot, Tooth, Hoffman, and himself. If the case were such, the findings in the spinal cord would have been of great importance. He was not yet certain whether the peroneal form represents a spinal disease or a peripheral affection.

Dr. Putnam had a case in an adult where there was rapid destruction of gray matter throughout the cord. Despite the violence of the process, portions of the anterior and lateral cell groups were preserved.

Dr. Preston inquired as to alterations in the blood-vessels. He believed this was the primary alteration in the pathological changes. He also asked if Dr. Collins had examined cross sections of the mixed nerves.

Dr. Gray thought it very difficult to make a positive clinical diagnosis between the central and peripheral portions of the lesion. This was often illustrated in the class of cases reported by Dr. Hammond.

Dr. Collins, in closing the discussion, said that his investigations extended over greater ground than his paper suggested. There was diminution in the size of the vessels, but no evidence of atheroma. The mixed nerves were not examined. He thought the hæmotoxylon stain useless for a study of the cellular structure.

Dr. Hammond concluded that the peroneal type was simply progressive muscular atrophy, beginning in the peroneal muscles.

Optic Neuritis, Blindness, Deafness, and the Knee-jerk in Cerebellar Disease.—Dr. F. X. Dercum, of Philadelphia, read a paper with this title. He thought many of the symptoms of cerebellar disease were both inconstant and variable. They are difficult of explanation and frequently impossible to correlate. He desired to call attention more especially to the optic neuritis, the blindness, the deafness, and the modifications of the knee-jerks. He related the history of seven cases in which the above symptoms were present.

It is a matter of common experience that very high grades of neuritis may exist without marked impairment of vision. It would seem, therefore, that the added symptom of blindness gives a special significance to the optic neuritis found in these cases. It would appear that for some reason if we have optic neuritis at all in cerebellar disease that it is apt to be intense in character, and, further, that it is likely to be associated sooner or later with total blindness. The proximity of the quadrigeminal bodies has naturally suggested itself as in some way explaining this blindness. The ataxia and titubation present in these cases refers us at once to disease of the vermiform process. A consideration of anatomy, as well as the autopsy of Case III., will show that if a growth be situated in the vermiform process, especially anteriorly, and that if this growth continues to enlarge, it will sooner or later press upon the superior cerebellar peduncles and very probably upon the quadrigeminal bodies themselves. When we recall the relation of the fibres of the optic tract to the primary optic centres, we can readily understand how, if pressure or irritation occur at this point, a neuritis should be a consequence. Further, the irritation being direct, we can, perhaps, understand why the neuritis should be of a high grade, and, finally, also why this neuritis should be associated sooner or later with total blindness.

With regard to the deafness which is present in some cases of cerebellar tumor, and which was absolute in Case III., it may perhaps be explained in a similar manner. The studies of Spitzka, Monakow, and others have made it extremely probable that the posterior quadrigeminal bodies stand in the same relation to the auditory fibres as do the anterior to the optic fibres. It would simply be necessary, therefore, to our explanation that the pressure involve these structures in order that deafness should be a symptom.

When we turn our attention to the knee-jerk, we meet with a problem of peculiar difficulty. It would seem that one would be justified in accounting for the loss of knee-jerk when observed in disease of the cerebellum by the loss of muscle tonus. It is extremely probable that lesions of the cerebellum act as do lesions elsewhere, in one of two ways: *i.e.*, either by destroying tissue, and thus destroying function, or by acting as irritants. It is perhaps in this way that we can account for the fact that in some cases of cerebellar disease the knee-jerk is absent, and in others present or exaggerated.

Dr. Gray hoped that Dr. Dercum's explanation of the symptoms would prove true, and asked if the pupillary reflexes had been observed.

Dr. Dercum replied that when the disease had advanced there was loss of reflex action to light.

Dr. Putnam spoke of a case of long-standing optic atrophy and practically no other symptom. Although the optic neuritis persisted for two years, the autopsy showed a cyst and tumor of the cerebellum.

Dr. Preston asked if distinct loss of muscular sense existed in Dercum's case. He had noted this symptom in two patients. In four of his cases the knee-jerks were irregular, disappearing and occasionally returning.

Dr. Knapp said that in all of his cases, confirmed by autopsy, there was neuritis or optic atrophy. In one case, where cerebellar tumor was suspected, neuritis had not developed. Blindness had not been so constant. In another case the light reflex was lost when the pupils became dilated. Pressure on the corpora quadrigemina was most likely to produce blindness. He had never noted deafness. As to disease of the middle lobe of the cerebellum being responsible for the ataxic gait, he thought this view untenable.

Dr. Leszynsky, of New York, said he had observed a number of cases; two with autopsy. He thought the concomitant basal meningitis had much to do with the production of the optic neuritis, by extension of the inflammatory process along the nerve-sheath. In many cases the neuritis was a late symptom. Where the neuritis or optic atrophy was accompanied by loss of light perception, the pupillary reflex was always absent.

Dr. Dercum did not believe the neuritis due to pressure, but more dependent on the location of the tumor. In his cases the neuritis was always of high degree. Neuritis, blindness, and deafness indicated pressure on the mid-brain. He would look for cerebellar symptoms where the knee-jerk was variable.

A New Method for the Reduction of Dislocation of the Cervical Vertebræ.—Dr. C. L. Walton, of Boston, in reading a paper upon this subject, said that since the publication of sixteen cases previously coming under his notice, he has seen several of similar character, leading him to the belief that this condition is not rare, though frequently overlooked. Reduction by extension usually attempted is unsuccessful. Spontaneous reduction has occurred, showing that direction is more important than force. This fact led him to the discovery of the method theoretically correct, as shown by manipulation of the vertebræ, and by experiments upon the cadaver made by Dr. Richardson, of Boston, and himself. The method has been recently demonstrated in practice by Dr. Beach at the Massachusetts General Hospital with successful result.

In illustration of the method: Suppose the left articular process of one vertebra has slipped forward over that of the vertebra below, and fallen into the depression an-

terior to the articular process. This bends the head to the left, and turns the face to the right. The reduction is accomplished by extending the head diagonally backward to the right, so as to elevate the articular process, after which rotation to the left replaces the displaced vertebra. The transverse processes on the right act as a fulcrum. The ligaments which hold the vertebra firmly in the false position make no opposition to this manœuvre, which requires no force. In bilateral dislocation the same movements should be made, first on one side, reducing it to unilateral displacement, then on the other.

Dr. Putnam said that cases are more numerous than supposed, and cited the instance of a man injured by a fall, who accidentally died through carelessness in his removal to a hospital.

Dr. Sachs asked if this method would be practicable in other than recent cases.

Dr. Walton replied that the operation was performed in one case of about ten days' standing. A case in which bilateral dislocation was produced spontaneously, with perfect recovery, would lead him to recommend the attempt at reduction, even after a number of months, should there be no doubt as to the diagnosis.

Second Day, Wednesday, July 26th.

Acromegaly, Gigantism, and Facial Hemihypertrophy.—Dr. C. L. Dana, of New York, read a paper with this title, and reported the history of a case of acromegaly with autopsy, also a case of gigantism or somatomegaly with some symptoms of acromegaly. The giant had a unilateral facial hypertrophy.

The first case was that of a full-blooded Bolivian Indian, who was exhibited as a giant. He was thirty years of age; height, 6 feet 7 inches; weight, 300 pounds. He had an enormous development of the malar and frontal bones. His thorax measured fifty inches in circumference. He died suddenly.

On autopsy the brain was found normal, weight fifty-five ounces; the pituitary gland was greatly enlarged, measuring one inch in diameter; thyroid weighed four ounces. The feet and hands had increased in circumferential measurements. The brain presented interesting peculiarities of fissuration.

The second case was a professional giant, 7 feet 5 inches tall, weight 350 pounds, age nineteen years. His muscular development was feeble. He had several symptoms resembling those of acromegaly. His most curious condition was a progressive unilateral facial hypertrophy, due mainly to osseous growth. It suggested an acromegaly attacking only half of one extremity. Only eleven cases of this affection are on record.

Dr. Dana said that acromegaly was sometimes associated with gigantism. He thought that many so called giants were instances of pathological growth, rather than excessive physiological development. There was much evidence to show that the pituitary gland had some function in these disorders. Among twelve autopsies, this gland was found enlarged in ten.

Dr. Dercum said that acromegaly is not associated with increase in the length of bones, but in their width. He regarded Dr. Dana's case as one of gigantism with acromegaly superadded.

Dr. Gray considered it a question whether acromegaly and gigantism are not identical. We are still in the dark as to the pathology of acromegaly. He thought the cases presented did not warrant Dr. Dana's conclusions.

Dr. Collins looked upon them as two separate diseases. In gigantism the changes are in the cellular structure of the diaphyses and epiphyses, principally the former. In acromegaly the changes are confined to the epiphyses. Probably the disease of the pituitary gland stands in proper relation to acromegaly. Much depends on the method of examination. He had destroyed the gland in animals to see if acromegaly developed; but all died. He thought giants may suffer from acromegaly, and regards it as a degenerative disease.

Dr. Brill, of New York, asked what structures in the brain were usually involved.

Dr. Collins answered the glandular structure of the pre-hypophysis.

Dr. Dercum expressed the view that as the other ductless glands are so often enlarged in acromegaly, to select a single gland as being enlarged seemed precipitate. No doubt the pituitary body may have important functions to subserve.

Dr. Putnam said that investigators have destroyed the gland in animals, producing polyuria, thirst, and debility. In view of the small number of autopsies, we cannot dogmatize. The gland was found normal in three out of nine reported cases.

He had seen temporary improvement in one case under the administration of thyroid extract. We are dealing with abnormities of development, and cannot expect to discover lesions as the cause. In ten autopsies that have been made, the thyroid was wasted in seventy seven per cent.

Dr. Sachs was of the opinion that both conditions are related. Gigantism is a form of physiological excess, while acromegaly is a distinct morbid condition. He did not attach much importance to the influence of the pituitary body, but thought our knowledge of the exact etiology and pathology is still in abeyance.

Dr. Weber, of New York, had seen two cases. One had symptoms of myxœdema. He was inclined to believe gigantism to be excessive physiological growth.

Dr. Mills had found at autopsy a tumor destroying the pituitary gland, but there was no acromegaly.

Dr. Dana, in closing the discussion, said we do not know the functions of the pituitary gland in its relation to acromegaly, but it is certainly of some importance. He still believes in the clinical relationship between gigantism and acromegaly, but looked upon gigantism as an irregular type. He regarded gigantism as a pathological condition. The thyroid was not enlarged in his case, but the pituitary gland was.

Thyroidectomy in the Treatment of Dr. Graves's Disease.—Dr. J. J. Putnam, of Boston, read a paper on the treatment of Graves's disease by thyroidectomy. After calling attention to the fact that this operation has been done some forty times, mainly by German surgeons, with but two deaths and a very large percentage of cures or improvements, the speaker narrated a case from his own experience. It was that of a young woman suffering from a typical form of Graves's disease, of nine months' standing, and with a rather large goitre. The right lobe and most of the isthmus were removed. During and after the operation the patient's pulse ran up very high, and for several days she lay in an extremely prostrated and apparently critical condition. She then rallied, and now, at the end of six months, her condition is decidedly better than before the operation, though she is far from being cured. The remaining portion of the tumor has not shrunk, and still shows a marked tendency to vascular enlargement. The voice was reduced to a whisper under the immediate influence of the operation, but has now nearly recovered its natural tone. This is not an unusual occurrence.

Dr. Putnam analyzed the reported cases from the following points of view: The immediate and remote effects of the operation (including the mortality rate after operation for goitres in general); the influence of the character of the tumor on the result; the degree and persistence of the improvement in favorable cases; the character of the operation.

Finally, the questions as to the nature of Graves's disease and the relation of the other symptoms to the goitre were discussed. It was pointed out that this relationship was probably based on the fact that the thyroid has important vascular functions.

Strong emotions are capable of causing temporarily most of the symptoms of Graves's disease. The reasonableness of the operation lies in the fact that in Graves's disease certain nervous centres are in a state of extreme

irritability. Any means which will cut off a considerable number of excitations from reaching the unstable centres is likely to be beneficial, by securing for them a partial physiological rest. There are various means, such as complete rest, the treatment of the naso-pharynx, etc., which may do this in a measure; but no one means is so effectual as thyroidectomy. The operation is, however, attended by a slight risk of death, and by a greater risk of considerable temporary prostration and laryngeal paresis.

Dr. Dercum had recorded the case of a man with all the symptoms of Graves's disease but the enlarged thyroid.

Dr. Weber had noted recovery in a patient possessing all of the characteristic symptoms under the persistent use of iodide of potash. The dose was gradually increased to three drachms daily.

Dr. E. D. Fisher thought it would hardly seem probable that in Graves's disease the enlarged thyroid can be considered as acting in a mechanical way in producing the symptoms. He had seen many cases in Canada, in whom apparently no symptoms were produced. These persons continued in their regular occupation without discomfort.

Dr. Putnam, in closing, said that a large number of instances of goitre without symptoms had been reported with autopsies. Such children in particular had suffered from debility, and there was dilated right heart. He gave a *résumé* of our present knowledge of Graves's disease, both experimental and clinical. He concluded that we have not sufficient data to establish a physiological basis for the disease.

Tabes and Syphilis.—Dr. B. Sachs, of New York, assumed that recent statistics of Erb and others proved the close relationship between syphilis and tabes. This was established, furthermore by: 1. The frequent occurrence of general paresis with tabes, and of tabes in the course of general paresis. 2. The occurrence of symptoms in the course of tabes which are often due to syphilis, the ocular palsies, loss of pupillary reflexes, and even the lightning pains. 3. The effect of mercurial and iodide treatment upon many of the symptoms of tabes.

The writer attempted a clinical differentiation of cases of tabes which are due to an active syphilitic process; among these he considers those which exhibit complete loss of reflex contractility of one or both pupils, and ocular palsies. He reported *in extenso* a case of typical tabes, in which, on post-mortem examination, a more recent syphilitic process was superimposed upon an old typical sclerosis. He next referred to the way in which syphilis might cause a spinal sclerosis. He gave reasons for thinking that this was largely due to degeneration brought about by syphilitic disease of the blood-vessels to the spinal cord. Altered states of the blood might be the prime cause of the change in the blood-vessels.

Dr. Preston regarded the syphilitic process as an arterio-sclerosis. Rarely is there hyperplasia of neuroglia without changes in the cells or nerve-fibres. The tabetic process probably begins in the blood-vessels. Traumatism seemed to be a most important etiological factor. He had seen improvement and relief of pain from the use of nitro-glycerine.

Dr. Mills looked upon the active lesions described by Dr. Sachs as probably causative of the sclerosis. Preceding the development of the sclerosis, there may be leptomeningitis and disease of the vessels, which if attacked early might be relieved or removed; but the sclerosis once established, recovery is impossible. Posterior sclerosis often advances at intervals by jumps, and these may be sometimes coincident with or may follow the revival of active syphilitic processes.

Dr. Parsons referred to two cases of syphilis followed by insanity and subsequent development of spinal symptoms.

Dr. Seguin still adheres to the idea that syphilis is only a predisposing cause for the groundwork of tabes. Certain cases occur that are undoubtedly free from any history or evidence of syphilis.

Dr. Knapp mentioned a case of primary syphilis being superadded to tabes of two or three years' standing.

Dr. Spitzka did not doubt that cases of tabes existed without syphilis. He had called the attention of the Association to the same pathological condition about eight years ago.

Dr. Walton thought the frequency of trauma in the production of tabes was overestimated. The ascending degeneration resulting from transverse lesions of the cord or from fracture can hardly be regarded as a typical tabes. If we could get at the real facts in all cases, the cases in which syphilis existed without our being able to elicit the history would more than counterbalance those in which we may mistake a chancroid for a sign of syphilitic infection.

Dr. Gray said there is an anatomical explanation for every symptom in tabes. In all cases he had seen he could differentiate between spinal syphilis and tabes.

Dr. Sachs did not claim that spinal syphilis is the same as tabes. We should never omit prescribing the most active anti syphilitic treatment in the early stages of tabes. He does not believe every case is due to syphilis. In the large majority of cases, syphilis is the prominent factor.

A New Pedodynamometer.—Dr. William C. Krauss, of Buffalo, exhibited a new pedodynamometer. The apparatus consisted of a wide heavy belt, its inner surface padded, so that its adjustment around the waist will not be uncomfortable. A heavy webbing is looped through the belt, passing over the shoulders, which helps to retain the belt in position. A common dynamometer is connected with the belt by means of a strong adjustable strap, permitting it to be lengthened or shortened, depending upon the stature of the patient. Connected with the dynamometer is a stirrup, the base of which is padded for receiving the foot. Pressure exerted upon the stirrup will be registered upon the dial of the dynamometer, and the exact strength of the extensors of the leg can thus be ascertained. The apparatus can be applied either in the standing or recumbent posture. The leg should be flexed about 90° at the knee. To tell the strength of the calf muscles, the strap should be lengthened and the foot flexed upon the leg.

Infectious Endocarditis with General Septicæmia, complicated with Multiple Neuritis.—This paper was a joint communication by Drs. James H. Lloyd and David Riesman, of Philadelphia. It was founded on the report of two cases. The first case was in a man who was admitted to hospital with a typhoid type of fever, which had continued for three months, and was complicated with multiple neuritis. The diagnosis of typhoid fever was excluded. The neuritis was irregularly distributed. The patient gradually developed an aortic regurgitant murmur, with water-hammer pulse. Later a purpuric eruption appeared. A diagnosis was made of infectious endocarditis with secondary septic neuritis. At the post-mortem immense vegetations were found on aortic valves, with infarcts in the spleen and in one kidney. Sections of the spinal cord and nerves were shown, exhibiting slight posterior sclerosis in the cord and extensive inflammation in the nerves. The second case, also in a man, simulated typhoid fever, with yellow-colored stools. At the post-mortem, multiple abscesses in the brain, a large embolus in the left brachial artery, and an infarct in one kidney were found, dependent upon a giant growth of vegetations as large as a pullet's egg, attached to the inner coat of the aorta, overhanging the orifices of the innominate, carotid, and sub clavicular arteries.

Dr. Dana regarded the septic origin of neuritis of much importance. He cited the case of a young man with symptoms of rheumatism not responding to antirheumatic medication. Pyelitis developed in two or three weeks, followed by multiple neuritis affecting all extremities. It is well known that multiple neuritis in this country is most frequently due to alcohol, and not of microbic origin. These forms of neuritis have a different

clinical history. Some cases have begun with a history of multiple neuritis, and have then shown symptoms of locomotor ataxia or other spinal-cord affection. There is a class of cases where the neuritis extends and ultimately involves the cord.

Dr. Dercum agreed with Dr. Dana's views, and believed posterior sclerosis occasionally follows multiple neuritis. He asked if septic symptoms preceded the neuritis in Dr. Lloyd's case, with history of alcoholism; to which Dr. Lloyd answered yes.

Tumor of the Angular Gyrus.—Dr. C. L. Walton, of Boston, reported a case of tumor involving the angular gyrus and extending into the temporal, occipital, and parietal regions. The symptoms were temporal and occipital headache, vomiting, paralysis of the left abducens from pressure, double optic neuritis, hemianopsia, word-blindness, asphasia, and word-deafness. Operation was attempted by Dr. Richardson, of Boston. The tumor, however, proved too large and diffuse for removal. The patient lived two months with comparative relief of pressure symptoms, including abducens paralysis. Toward the end, the right hand and arm became somewhat paretic. The autopsy showed the growth to be a glioma.

Dr. Seguin suggested that the ocular symptoms were probably not due so much to lesion of the angular gyrus as to involvement of the fibres of the fasciculus opticus, which lie immediately under it. The lesion being rather deeply placed must necessarily involve the white fasciculi.

Dr. Walton agreed with Dr. Seguin that the hemianopsia was due to affection of the optic radiations on their way to the occipital lobe. The early appearance of mind-blindness, together with red spots in the field of vision, suggested early cortical irritation in the region of the angular gyrus. If the symptom mind-blindness is considered due to affection of association fibres we are justified in assuming the association fibres implicated to be those running to the angular gyrus.

Congenital Cerebral Hemiplegia, with Autopsy.—Dr. E. D. Fisher, of New York, read the history of a case of infantile cerebral hemiplegia of congenital origin. The symptoms were a complete right hemiplegia, with marked atrophy and exaggerated reflexes, epilepsy, and imbecility. The cranial measurements showed morbid deficiency in the binauricular diameter and facial length. At the autopsy the left hemisphere was found much atrophied. The right cerebellar hemisphere was also atrophied. The microscopical specimens showed a decrease in the number of cortex cells, but those present were not much diminished in size. There was some loss of acuteness of the angles of the cells, but little pigmentary or granular changes. The cord was but slightly affected. He believed that this would seem to show that in some cases we may have a fair amount of normal cerebral structure even when there is such pronounced cerebral disease.

Dr. Sachs said that in the cases in which motor areas present developmental defect, degeneration does not necessarily occur.

Lesion of the Thalamus and Internal Capsule.—Dr. Charles K. Mills, of Philadelphia, contributed the notes on a case in which there was a lesion of the thalamus and internal capsule. The patient had an apoplectic attack in 1877, and died in 1892. The symptomatology of the case summarized was hemianæsthesis; paresis with contractures not marked; inability to recognize position of the affected limbs. Hemianopsia and all affections of the special senses were absent, as were also athetoid and choroid movements. Autopsy showed a hemorrhagic cyst which had destroyed about two-thirds of the substance of the thalamus, including the entire external tubercle, and a large portion of the pulvinar. The anterior extremity, and the internal and inferior surfaces of the thalamus were intact. The lesion has invaded, to a slight extent, the posterior arm ot the capsule.

Tumor of the Optic Thalamus.—Dr. Wharton Sinkler, of Philadelphia, read a paper on this subject, and presented the specimen from a case with the following history:

The patient was an unmarried woman, forty-six years of age, who was in excellent health up to January, 1893. Her first symptoms were somnolence and loss of mental vigor. Her manner was indifferent and listless. In April there was some aphasia, and, later, paresis of the right side of the face, unsteadiness of gait, and awkwardness in the use of the right hand. When first seen by him there was marked paralysis and partial anæsthesia of the right side of the face, but no impairment of sensation of the arm or leg. There was decided mental hebetude but no loss of memory. She could not walk on account of unsteadiness. The knee-jerks were exaggerated. The temperature was subnormal, and the pulse from 48 to 60. The pupils responded to light and accommodation. There was no nystagmus or hemianopsia, and no change in the fundus oculi. The symptoms increased in severity, the temperature rose rapidly, and the patient died May 25th. There had been no convulsions.

Post-mortem showed skull and membranes healthy. Cortex normal in color and consistency. The left optic thalamus was the seat of a growth as large as a hen's egg, which encroached upon the corpus striatum and posterior part of the internal capsule. The tumor has not been examined microscopically, but is probably a fibroma.

The points of interest are the hysterical symptoms which were present at the onset; the fact that the anæsthesia was confined to the face, and the question which arose as to the possibility of operation.

These two papers were discussed together.

Dr. Dana had two cases, one with tumor and another with softening in that region. Somnolence was a prominent symptom. The phenomenon of somnolence is characteristic where the posterior portion of the optic thalamus and the neighborhood of the corpora quadrigemina were involved.

Dr. Seguin observed a patient, with probable tumor in this locality, with somnolence, which was increased by the use of iodide of potash. He asked if such effect of the iodide had been observed by any of the members present.

Dr. Dana was familiar with a case where the iodide acted as a hypnotic.

Dr. Gray had noticed that iodide had produced somnolence in a case of cerebro-spinal meningitis.

Dr. Leszynsky thought that iodide only acted indirectly as a hypnotic by relieving the pains of syphilis.

Dr. Sinkler remarked that in his case the somnolence diminished after the administration of the iodide.

The Localizing Value of Aphasia.—Dr. George J. Preston, of Baltimore, read a paper upon this subject and called attention to the fact that aphasia has hardly commanded its proper place in the domain of cerebral localization. The centres for the speech processes, and the visual and auditory centres were described. In connection with word-blindness two cases of hemianopsia were related, one with autopsy, in which there was no word-blindness, as might have been expected. A case of mixed aphasia was related and the brain exhibited. The case showed absolute motor aphasia, together with word-blindness, and yet the lesion was confined to the third frontal convolution; the occipital cortex showing no disease. The general value of speech disturbance, as an aid to localization, especially in disease or injury of the brain, was discussed. A case was reported in which there was a general speech disturbance, with distinct mental symptoms; patient was at times maniacal. Upon the strength of the general disturbance of the speech processes the skull was trephined over Broca's region and the under surface of the dura found covered with blood. This case was mentioned to show how valuable speech disturbances may be, although very general in nature and not belonging to any recognized variety of aphasia.

Spinal Neurasthenia.—Dr. Leonard Weber, of New York, presented a contribution upon this subject. He objected to any single plan of treatment as too much routine, and not likely to be of permanent service to the

patient, while a proper combination of the well-known methods, based upon careful individualization, were apt to be of greater benefit. In the grave forms of neurasthenia caused by mental and physical overwork, the prognosis so far has not been good, even as to relative recovery. If the reports can be trusted it would seem that we have in hypnotic suggestion a remedy of extraordinary power in some of these cases.

In conclusion he related the history of some cases of severe neurasthenia brought about by protracted mercurial inunction, and another case caused by prolonged daily use of small doses of Carlsbad salts. Both recovered at the end of about a year.

THIRD DAY, THURSDAY, JULY 27TH.

Observations in a Case of Myxœdema.—DR. WILLIAM C. KRAUSS, of Buffalo, read a paper with this title. He reported a case of myxœdema in a woman, fifty-three years of age, whose mother was afflicted with symptoms similar to the patient's. The patient had always been in good health up to her forty-sixth year, although she had never perspired, and the secretions—as saliva, nasal mucus, and milk—were always scanty. Following upon an accident her face, body, and extremities became swollen, her hair suddenly disappeared from all parts of the body, and she was troubled with severe pains, especially through the temples, and a tired, all-gone feeling, incapacitating her for all kinds of manual labor. She further complained of a feeling of coldness even in midsummer. Her hands were dry, harsh, and scaly; her face waxy, and her eyes puffy and swollen. Her temperature ranged from 95⅘° to 97⅘° F. Her pulse, soft, regular, and uniform, varied from 81 to 88 per minute. The œdema-like swelling did not pit on pressure. Urine normal, no albumin at any time. The only drug that acted beneficially was the perchloride of iron. The author experimented with thyroid glands of sheep, feeding her for six weeks, but could detect no improvement whatever. Another case, seen in consultation, was being treated with dessicated thyroids, also without benefit.

Simulation in Traumatic Nervous Diseases.—DR. PHILIP COOMBS KNAPP, of Boston, in reading a paper with this title, said that although many men will simulate disease if it be to their advantage, we rarely find successful simulation of the various traumatic nervous affections. Until recently few cases have been reported by neurologists; most of the old cases were reported by general practitioners whose knowledge of nervous diseases was limited. In non-traumatic hysteria and neurasthenia we see many symptoms which would lead us to judge that the symptoms did not really exist. Many persons unjustly accuse the victims of these diseases of pretending to be ill, when really the malady is a serious one. Contraction of the visual field, anæsthesia, tremor, disturbances of the reflexes, circulatory disturbances, and Mannkopf's symptom are to be regarded as important objective signs. Few simulators can have intelligence enough to withstand a searching examination by a skilled neurologist. Furthermore, a man can keep his attention fixed on any subject only for a very brief time; and if he must be prepared to defend his simulation of half a dozen different symptoms, he will inevitably be tripped up by unexpected tests applied when his attention is diverted.

Three cases were cited in which the defence claimed that there was simulation, but in every case objective evidence proved the reality of the disease. Out of fifty cases where claims for damages had been brought forward, only two could be regarded as simulating, and few as exaggerating, and in most of these there was little reason to suppose any deliberate attempt at fraud.

DR. MILLS believed absolute simulation very infrequent. The cumulative exaggeration of symptoms was comparatively frequent however. A few people can simulate a type of insanity or traumatic neurosis, but cannot easily simulate all the symptoms and signs. He is in favor of the convex-lens test for amblyopia, instead of prisms in these cases. He does not consider malingering of common occurrence.

DR. GRAY thought many cases supposed to be simulating are simply offering to the trained eye symptoms indicative of possible simulation. He related a case of traumatic neurasthenia cured by $\frac{1}{12}$ grain of atropine taken for two days.

DR. FIELD considered simulation rare. Gross exaggeration was common in these cases. In almost all there is some exaggeration of the symptoms.

DR. LLOYD, regarded the symptoms of traumatic neurasthenia as nothing but the inter-paroxysmal symptoms of hysteria. Because a man develops hysteria after an accident there is no reason to believe that he must be a simulator.

DR. SEGUIN said the influence of the attending physician is often pernicious to the patient. He may not actually coach him, but he suggests. Some patients take advantage of a pre-existing morbid affection. The absence of treatment is responsible for a continuance of the symptoms of traumatic nervous affections. We should be allowed to examine these cases unexpectedly, unguardedly, and thoroughly, and not when sympathetic physicians or counsel are present. He protested against Dr. Lloyd's remarks about the unity of hysteria and traumatic neurasthenia.

DR. KNAPP, in conclusian, said that he sees cases with minor exaggeration, in contrast to Dr. Field's cases of the grossest exaggeration. He agreed with Dr. Seguin regarding the absence of treatment, but he has had a number of cases where treatment had been early and properly instituted. He could not agree with Dr. Lloyd's style of nomenclature.

DR. SEGUIN exhibited a specimen stained with 1 to 2,000 nigrosin, a method he had used years ago, but neglected to publish. One of the advantages was that specimens may be safely left in the solution for twenty-four hours.

The Microbic Origin of Chorea, with a Case.—DR. C. L. DANA, of New York, read the history of a case of chorea with autopsy. The patient was a man of twenty-six, and had had chorea since the age of fifteen. The attacks came exactly like those of the ordinary chorea of Sydenham. At first there were intermissions, but the disease finally became chronic. The spasmodic movements were general and violent. There was no heart disease or rheumatism. The patient died from exhaustion. Autopsy showed macroscopically a conspicuous chronic lepto-meningitis involving the vertex of the brain. Microscopically this was found to be mainly a proliferation process, without exudation or much cell infiltration. In the superficial layer of the cortex there was cellular infiltration and degenerative changes. At this point a diplococcus was found. Full details were given of this by Dr. Brooks, the bacteriologist. The microorganisms were found only in the deep layer of the pia and the superficial part of the cortex. In addition there was found peculiar hyaline bodies in the three outer layers of the cortex, and less numerously in the basal ganglia. There were evidences of meningeal irritation, vascular disease (arteritis), and nerve-root irritation in the medulla and upper part of the cord. The lower part of the cord was not examined.

Election of Members.—The following-named gentlemen were elected to active membership: Dr. Brower, of Chicago; Dr. Burr, of Philadelphia; and Dr. Diller, of Pittsburg. Dr. Arnold Pick, of Prague, was elected an associate member.

Papers by Title.—"The Genesis of Hallucination, Illusion, and Delusion," by H. A. Tomlinson, M.D., of St. Peter, Minn.; "The Diagnosis of General Paresis," by L. C. Gray, M.D., of New York; "A Report of Two Cases of Friedreich's Disease," by Frank R. Fry, M.D., St. Louis, Mo.: "The Metapore or Foramen of Magendie in Man and in the Orang," by Burt G. Wilder, M.D., of Ithaca; "Observations on the Relation of

Chorea to Rheumatism," by C. Eugene Riggs, M.D., of St. Paul; "Experiences in the Use of Testiculine and Cerebrine," by J. J. Putnam, M.D., of Boston; "Peripheral Paralysis after Surgical Operations," by V. P. Gibney, M.D., of New York; "Traumatic Brachial Plexus Paralysis in Infants," by William M. Leszynsky, M.D., of New York.

Election of Officers.—The officers elected for the ensuing year were: *President*, B. Sachs, M.D., of New York; *Vice-Presidents*, F. X. Dercum, M.D., of Philadelphia, and P. C. Knapp, M.D., of Boston; *Secretary and Treasurer*, G. M. Hammond, M.D., New York; *Councillors*, E. C. Seguin, M.D., of New York, and J. H. Lloyd, M.D., of Philadelphia.

In the evening a banquet was given by the Association at which nearly thirty members were present.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

APPROACH OF CHOLERA—THE DRESDEN CONFERENCE—ABANDONMENT OF QUARANTINE—EXERCISE OF SUPERVISION—DISINFECTION—STEAM OR DRY HEAT—LAUNDRIES—THE REPORT OF THE LUNACY COMMISSIONERS—IS LUNACY INCREASING?

London, July 22, 1893.

In various parts of the Continent cases of cholera are reported, and on the 19th a steamer from Marseilles, on arrival at Cardiff, had two cases on board. They were removed to the isolation hospital, the vessel disinfected, and kept for a time under observation by the sanitary officers. During the next few weeks we are likely to have several recurrences of this sort of event, and it is during those weeks that an epidemic is most likely to establish itself. It is natural, therefore, that some anxiety should be manifested by the public. Our sanitary authorities seem to realize their responsibilities, and probably we have never before been so well prepared, and yet the abandonment of quarantine and its horrors practised by England is being followed more and more. Thus one result of the Dresden conference has been to establish the value of the British precautions against that of quarantine. In fact, a great advance in this direction has been made in Europe in consequence of the example of England in refusing to sign a convention adopting quarantine. In 1866 the Constantinople conference recommended ten days. In 1874 the Vienna meeting reduced this period to seven days; and in 1885 at Rome a period of five days was adopted. Now, we have at last agreed to a convention which leaves other nations at liberty to follow or not the example we have so long set. In this convention the minimum and the maximum of restrictions to be imposed as regards land and sea traffic and goods are duly defined, and between these limits each country will exercise its discretion. Needless to say that it is well understood that England will not exceed the minimum. Indeed our delegates had to exercise all their influence to restrict this minimum as much as possible.

A point of great importance was that relating to arrivals in infected ships. The great majority held that healthy persons ought to be placed under observation for five days. This was only accepted by England on the understanding that the supervision would only be exercised by us after these persons had returned to their own homes. Some other precautions were agreed to, the result being that, so far as the British isles are concerned, quarantine is in no way resuscitated, and on the Continent it seems in a decline.

An analogous subject to the preceding is disinfection; and on this some important observations appear in the report of the medical officer for the County of London. Every sanitary authority is required by the Public Health (London) Act to provide for proper disinfection. Sixteen districts employ steam, fourteen dry heat, and two employ a contractor who uses steam. It is at least doubtful whether this work should be entrusted to contractors, and I notice that the medical officer does not seem to favor the plan. With regard to the relative value of steam and dry heat, the following fact may be quoted: In the Chelsea dry-heat apparatus a feather-bed left in for six or seven hours only attained a temperature of 120° F. in the centre; whereas in the steam apparatus used in another district the centre of a bed left in for half an hour reached 250° F. The medical officer suggests the erection of two or three laundries in London, to which the sanitary authorities could send clothing to be boiled and returned, clean, to their owners; to which also households nursing their sick at home could send infected articles. For the disinfection of rooms sulphur continues the favorite. There are many other items of information and suggestions in this report.

Another interesting report, just issued, is that of the Lunacy Commissioners; but I have only space to notice the question of the increase of insanity. Is that real or only apparent? The question has often attracted public attention, and sometimes very sensational statements have been made. When the commissioners began their work, forty-seven years ago, there were rather more than 20,000 lunatics in asylums. Now, according to this report, there are 89,822. Of these 8,200 were private patients; 80,893 were paupers, and 729 were criminals. During the year there was an increase of 2,055 of the paupers, but a decrease of 73 of the private class, and of 8 among the criminals. This gives a total net increase of 1,974, equal to two and one-fourth per cent., since last year, which is a somewhat higher ratio than usual. The death-rate and recovery-rate were lower, which accounts for part of the increase; but deducting these and other causes, the commissioners still find a residual increase of 1,079. In explanation they observe that certain constant influences conduce to the annual increase of lunatics in our asylums, such as, 1, the large proportion of incurables among the admissions, *i.e.*, patients who do not recover and remain until they die; 2, the difficulty of obtaining homes for cases of a somewhat more favorable type, who also do not recover, but so far improve that continued residence in an asylum is not otherwise necessary. The friends are too poor to receive them, and the Poor Law Guardians reluctant. Moreover, the public has so much confidence in the asylums that many lunatics above the status of paupers are placed in them, their relatives reimbursing the guardians the cost of their maintenance. To such causes are attributed the constant accumulation of chronic cases in the asylums. With this increase there is, however, a constant decrease in the number of lunatics kept in workhouses or as resident out-door paupers. After this it is not surprising to find that in some counties there is a deficiency of asylum accommodation. The boarding-out system has been successful in Scotland, but I doubt if it will become popular in England for insane patients. The question will arise whether persons above the status of paupers ought to be registered as such and the cost reimbursed to the guardians. It would be more in accordance with the national character for independence to permit their admission to the asylums without the stigma of pauperism, on a payment that would defray the actual cost or a little more, according to the financial resources of the relatives.

THE LATEST ELECTROCUTION.

To the Editor of the Medical Record.

Sir: As one of the physicians in official attendance upon the recent electrocution of William G. Taylor, at Auburn, upon July 27, 1893, our experience may prove worthy of more than passing notice when viewed scientifically, and perhaps valuable as establishing some data regarding accidents from contact with industrial currents that are so liable to occur now that alternating currents of high tension are so generally employed.

The writer, with Drs. Conway, of Auburn, Mooney, of Syracuse, and Wright, of Skaneateles, were requested by Warden Stout to assume charge of the execution, and together with the other witnesses proceeded to the electrocution chamber at 12.40 P.M. We were barely seated when electrician Davis turned the current through the bank of incandescents resting in the chair, the voltage registering 1,260 and everything working satisfactorily. The warden now retired and immediately returned with the condemned firmly held by the arms by two keepers and followed by Rev. Fathers Netzel and Seymour, of Auburn, reciting the prayers of the dying. Taylor walked firmly and seated himself in the chair with a wonderful firmness of demeanor, and even bent his head observant of the manner in which the attendants attached his legs to the supports and arms of the chair. All retired from the platform, the signal was given, and with a crash the legs shot forward and upward, tearing the standard and entire front from the chair. For exactly fifty-two seconds this condition was sustained, and at 12.47 P.M. the current was shut off. The condemned now pitched forward, and would have fallen upon his face had he not been restrained by the straps. For twenty seconds he remained apparently dead, a slight froth oozing from the mouth below the mask, when, to our horror, he gasped. The signal was again given, but no current responded to the rapid working of the lever. At the announcement by the electrician that no current was available, Dr. Mooney stepped to the side of the victim and could feel no pulse. Perhaps thirty seconds after I found a slight thready pulse upon the opposite side. Respiration had now increased to six to the minute and the pulse became stronger. During delay incident to procuring of a cot improvement continued. We unbound him and laid him upon the cot and removed him to an adjoining room, respiration now numbering 12 or 13 and pulse 100 and full; breathing stertorous and features possessing the idiotic, vacant expression seen in apoplectic seizures. Breathing continued labored but increasing in frequency, and at half an hour after contact was 18 and pulse 120 and full. He now made the first movement of left foot and in a very few moments became restless, moving legs and arms and rolling from side to side. Dr. Conway now administered ¾ grain morphia hypodermically at 1.18 P.M. After fifteen minutes, no appreciable effect being produced, the writer applied the cone saturated with ¼ chloroform and ¾ ether. He opened his eyes and tried to object to its administration at 1.36. Forty-eight minutes after contact pulse now numbered 130 and was full and vigorous. He readily responded to anæsthetic and was placed in the chair and second contact was made at 1.55 P.M. This continued forty seconds, and examination then proved him dead from a voltage of 1,220.

Autopsy at 3.30 P.M. by Drs. Brown, who examined the thorax and abdomen, and Wright the brain; present, Drs. Conway, Mooney, and Burrel, of Canandaigua. The body measured five feet seven inches, and weighed probably one hundred and forty pounds. Was well nourished and extremely muscular. Complete absence of "rigor mortis." Slight eschar upon each temple. Extensive eschar upon calf and nearly entire circumference of right leg (not present after first contact when hypodermic was given). A peculiar condition existed in the abnormal warmth of entire right leg as compared with rest of body or even our own. Muscles upon abdominal section very firm and almost complete absence of fat, which in view of prolonged confinement, seems remarkable. Slight congestion of peritoneum and coats of bowels. Spleen, stomach, kidneys, liver, all normal. Examination of thorax showed lungs slightly congested at apex. No pleuritic adhesions. Pericardial sac contained an ounce of serum. Heart normal in size. Valves intact, but studded with minute vegetations from former endocarditis. Blood fluid throughout. Brain not congested. Dura mater firm but not adherent. Upon section appeared normal. Skull more than normally thick.

To summarize, 1,260 volts passed for fifty-two seconds through the body with entire absence of heart's action at first observation, but within a few seconds becoming marked, and entire absence of motion for exactly half an hour, and with undoubted return of consciousness within the next twenty minutes without resorting to any means for resuscitation. The unfortunate accident was valuable in teaching the authorities that in connection with electric plant established by the State, the advisability of having city system attached to the switchboard, whereby the mere turning of a switch would obviate a repetition of this accident and yet not entail the expense of a duplicate system. The chair also should be strengthened upon the front and properly braced with bolted attachments, not screwed down, as in this instance; contact should be made by properly insulated metal plates attached to the arms of the chair, the bare feet resting upon properly insulated metal plates, thereby obviating the extra resistance of hair and cranial bones, for while the abnormal muscular development in the present case might not be present again, yet no chances should be taken. Notwithstanding the objections raised by the many opponents of the system and in the face of the unforeseen combination of circumstances present in this instance, it is to-day by far superior as a scientific means of execution to any heretofore devised. Too much credit cannot be given Warden Stout for the expeditious manner in which he solved the problem and introduced other means for the completion of the mandate of the courts and so as not to prolong the agony or further torture the condemned.

J. W. Brown, M.D.

Motteville, N. Y., July 27, 1893.

POST-MORTEM CHILD-BIRTH.

To the Editor of the Medical Record.

Sir: In your issue of July 29th is an account of a "birth in a coffin." Several years ago I saw a similar case at Bellevue deadhouse.

The body of a woman had been brought to the place in a coffin, where it was left awaiting transportation to the city cemetery for interment. This was during a very hot spell in the summer.

On examination of the body, some time after it had been received, it was noticed that a child had been expelled from it. The funis was still attached, unbroken, and the placenta had not left the mother's body.

The cause of the expulsion was very evident. The gases of decomposition had distended the abdomen enormously, and without doubt exerted sufficient pressure to drive out the child. It lay between the woman's thighs, quite in the same position that it would have assumed if the birth had taken place in the ordinary way.

These cases seem to me to possess a medico legal interest. It is within the range of probability that a child delivered in this way and found in a grave, with no record of its interment there, might become a very mysterious affair, and perhaps lead to a suspicion of crime. While, in the two cases now reported, the presence of a second body is explainable, it is quite possible that under some other circumstances it would not be so easily accounted for.

Wooster Beach, M.D.

New York.

A DISTINGUISHED CANADIAN.

To the Editor of the Medical Record

Sir: Dr. Jean Lukin Leprohon, A.M., M.D., C.M., of Montreal, celebrated his semi-centennial, May 26th last, as a graduate in medicine and surgery of the Medical Faculty of McGill College, Montreal.

The subject of this sketch was born April 7th, 1822, at Chambly, Province Quebec. He received a thorough education, finishing his classical study at Nicolet College, P. Q. He then entered on the study of medicine at McGill College, graduating May 26, 1843. He then visited Europe, for further study and travel, returning to Canada in 1845, when he commenced practice.

Of the graduating class of that year but two are living —both distinguished French Canadians—Dr. Leprohon, and the Hon. Charles Boucher de Boucherville; the latter never practised, but entered politics, and has attained distinction.

Dr. Leprohon's trend was essentially scientific and literary. He founded *La Lancette Canadienne*. In 1870, he was appointed Professor of Hygiene, in the Medical Faculty of Bishop's College, Montreal. Has been a justice of the Peace; Surgeon of Militia. Is one of the founders of the Women's Hospital, Montreal, and a Consulting Physician to the Montreal Dispensary. In September, 1890, the Lieutenant Governor of the Province of Quebec appointed him a member of the Roman Catholic Council of Public Instruction for the Province of Quebec.

Dr. Leprohon, for twenty-two years past, has been a vice-consul of Spain. When the vice-consulate in Montreal was raised to the dignity of a consulate general, the then Consul General there (now of this city), Señor Don Arturo Baldesano Topete, paid Dr. Leprohon the compliment of confirming his rank—an exception to the rule, as in Spain's diplomatic service, vice-consuls are not attached to consulates general. For his care and protection of Spanish interests he was made a chevalier, and received the Decoration of the Order of Charles the Third of Spain.

In 1851, Dr. Leprohon was married to Miss R. E. Mullins, a native of Montreal. At the early age of fourteen she evinced a marked inclination for writing and literary pursuits. Her early promise was confirmed. She became an accomplished and talented authoress, whose graceful writings over the initials R. E. M. are historic in Canada.

Dr. Leprohon is in full health and active practice. To have known him is a lasting pleasure, as he is characterized by that gentleness and urbanity that invariably attracts and makes many lasting friendships.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 5, 1893.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	18	5
Scarlet fever	39	4
Cerebro-spinal meningitis	8	6
Measles	169	8
Diphtheria	93	23
Small-pox	5	0
Cholera	0	0
Varciella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Treatment of Diphtheria with Serum.—Behring (*Deut. Med. Woch*, April 27th) discusses the action and dosage of the diphtherial immunized serum, and gives the results of its trial in 30 cases. The material used in these cases was a serum to which he applies the term "normal diphtherial therapeutic serum." Of the 30 cases, 24 recovered and 6 died, a mortality of twenty per cent.—Kossel (*ibid.*) gives full details as to 11 of these cases which were treated in the Infectious Disease Institute (Koch's) in Berlin. Two of the cases died; both were very severe cases, and reasons are given for believing that in one, aged four, death was due to septicæmia; in the other, aged three, it was necessary to perform tracheotomy immediately after admission, and the patient died four days later with extensive infiltration of the wound and cyanosis. *Post mortem* it was found that the membrane had extended into the bronchi and that tuberculosis also was present. Among the 9 cases which recovered were 3 in which tracheotomy was performed. These three children were aged three, nine, and five years respectively, the last being a very severe case with albuminuria and cyanosis. In 6 cases the membrane was present chiefly on the tonsil. In estimating the value of the serum, Kossel lays stress on the fact that three out of four cases recovered after tracheotomy—a very unusually high proportion. The serum was injected under the skin of the front of the chest. In every case but one the quantity given at the first injection was 20 c.c.; at subsequent injections—and in the eleventh case on the first occasion—the quantity used was 10 c.c. The largest number of injections in any one case was five, the quantity of serum injected being 50 c.c.; in this case the injections were given on admission, on the two following days, and on the fifth day. Gentle massage of the skin was used after the injection; beyond slight tenderness at the point of injection no unpleasant effects were noted. Behring and Boer (*ibid.*, May 4th) relate experiments on guinea-pigs with sheep's serum preserved in carbolic acid. This serum was found to be effective against (1) infection shortly after (2) poisoning with the soluble products of the diphtheria bacillus. It was curative (3) in cases in which the animal was already suffering from the disease or (4) from the symptoms of diphtherial poisoning. The dose required to accomplish (3) is twenty to one hundred times that necessary for (1); for (4) about six times that for (2).—*British Medical Journal.*

Cures for Obesity.—The theory of Hippocrates was that corpulence could be cured by inciting vitality. His prescription was much exercise, fasting, no hot baths, and life in the open air. Galen favored the same treatment, with a diet of vegetable acids, aperients, and frequent baths, combined with exercise and frequent rubbing of the body with coarse towels. After this school came the physicians of a few centuries ago, who believed in bleeding. Their theory was that abstraction of blood would free the heart and work off the fat. This theory did not work, as loss of blood weakened the circulation, and a feeble circulation is one cause of obesity. Among remedies for too much fat is that of Borelli, who advised the chewing of tobacco; Fleming, who prescribed a nightly dose of soap in four ounces of water; Darwin, who suggested the use of salt; Brown, who advised the exclusive use of animal food; and of Regneller, who prescribed friction and the rubbing in of ether and laudanum over the stomach. The modern school of physicians to cure corpulence began with Banting, about thirty years ago. He reduced the diet, restricted it, and insisted on the patient's taking a great deal of exercise. There was no doubt that this method achieved results, for if a man would stop eating and take enough exercise he would either die from exhaustion or lose all his surplus weight. Banting's system worked pretty well with people of sluggish temperaments who were not subject to nervous disorders, but for nervous people the treatment was too radical.

A Delusive Advertisement.—Some crafty person recently caused to be inserted in *The Lancet* an advertisement of a medical practice for disposal, which turned out, when answered by one of its readers, to be a bait with which a matrimonial agent was angling for a possible husband in the interest of a young widow described by him in glowing terms. The glowing terms doubtless did nothing but bare justice to the widow's graces and accomplishments. The description, however, did not impress the person to whom it was sent, and he turned over the correspondence to the editor with indignant comments of his own. If the lady be wise, she will probably now adopt some less adventurous plan of bringing her personal recommendations under the notice of possible admirers.

Scarlet Fever is still very prevalent in London, and the hospitals are so overcrowded that many patients are turned away for lack of accommodations.

CHOLECYSTOTOMY, WITH REPORT OF TWO CASES.[1]

By WILLIAM S. CHEESMAN, A.M., M.D.,

AUBURN, N. Y.

FELLOW NEW YORK ACADEMY OF MEDICINE, HON. MEMBER ONONDAGA MEDICAL SOCIETY.

Thirteen years ago Van Schueppel wrote:[2] "The idea of combatting permanent occlusion of the excretory (bile) ducts by surgical operation has at various times been either merely referred to or discussed in a definite shape. These discussions have hitherto led to no results." Scarcely a better illustration could be found of the fact that textbooks and encyclopædias of medicine fall so quickly behind the times as to be largely valueless a decade after publication. No cases receive more certain, safe, and enduring relief at the hands of modern surgery than do those of gall-duct obstruction.

It is the number, whereabouts, and behavior of gall-stones which determine the clinical history of these cases. Lying quietly in the gall-bladder, calculi may cause no symptoms whatever; or, at most, vague distress easily explained as dyspepsia. Nothing is commoner at autopsy than collections of stones in cases which have never been made aware of their presence. Why large numbers sometimes give no trouble, while in other cases a small number render life not worth living, or take it away altogether, is not yet explained.

A stone entering the cystic duct will promptly determine the pain characteristic of biliary colic. This pain is usually epigastric,[3] while tenderness is felt in the right hypochondrium over the gall-bladder. If the obstruction endure sufficiently long, the secretions of the inflamed gall-bladder accumulate, and a tumor is formed. The weight of this swelling may, as Riedel points out,[4] pull down the liver margin into a tongue-like process reaching below the umbilicus, and here felt with the enlarged gall-bladder behind. When found, this is most valuable as a diagnostic point. When not found, it is a colic without icterus which constitutes the sole symptomatology. The difficulty of distinguishing between this and an ordinary sharp intestinal colic or a gastralgia, has been repeatedly emphasized; yet this is often the whole case. Probably, however, time and a cathartic would enable us to rule out mere intestinal colic, while the stomach-tube might settle the question of gastric disease. Certainly no operation need be undertaken till these points can be determined.

If the stone progress to the common duct and block it, then follow the classical symptoms of bile obstruction. Jaundice, clay stools, dark urine, add themselves to the pain, tenderness and (perhaps) cystic tumor and tongue-like prolongation of the liver, which had announced the calculus in the earlier stages of its career. Clinical symptoms are not, however, always in direct ratio to local disease. They may be as stormy in a case of normal gall-bladder and small stones as in empyema with large calculi. William Osler[5] calls attention to a congeries of symptoms which he terms "Hepatic Fever," and regards as characteristic of stones lodged in the common duct. These are ague-like paroxysms, a chill, fever, sweat, with pain and gastric disturbance, and deepening jaundice. Osler is hopeless of any but surgical measures in such cases.

On this question of surgical intervention the balance of opinion favors trusting little to nature. To be sure, she does clever things. Stones lodged in the bladder or ducts may ulcerate into the outer world by direct or devious paths through the parietes, or into the intestinal canal, and so out. But nature's surgery too often stultifies itself. Post mortem records give many instances of huge monoliths reaching the gut after long stress of suffering, only to obstruct it fatally. Some twenty-one cases of intestinal occlusion from this cause have, according to Badouin's table,[1] come to operation. Sometimes, also, the ulceration tract opens into the peritoneum. With these contingencies in mind, one may be pardoned for not putting unquestioning reliance on nature and her methods.

The indications for operation now generally accepted are:[2] Chronic cholelithiasis, evidenced by steady icterus, pain, etc.; repeated attacks of colic and icterus; lasting pain, without icterus (cystic duct); retention swelling of the gall-bladder, whether empyema or hydrops. These may be summarized by saying that, whenever life is endangered or made seriously uncomfortable, operation should be considered.

Many are coming to regard the milder symptoms as good ground for operation; arguing that secondary changes, impaction, ulceration, catarrhal and suppurative biliary cystitis, even development of cancer, are thus avoided. To those who have witnessed recoveries from grave forms of cholelithiasis made without aid of surgery, this will seem extreme ground. So that here, as elsewhere, conservatism and radicalism are at strife. It is probable that few will follow this advanced teaching, and yet the responsibility which rests on him who, recognizing the presence of calculi, yet temporizes very long, cannot be avoided.

Several operation methods are at our disposal. The external incision is by some made along the outer border of the right rectus muscle; by others, parallel to the costal cartilages; while Czerny[3] recommends a ⌊ shaped cut, which allows of a flap being turned back.

The first question after exposing the gall-bladder is: Should it be opened? If stones exist, and are small and friable, they can be crushed by the fingers or the rubber-covered blades of a pair of forceps, after which the fragments escape spontaneously by the ducts. Cholelithotripsy has been done successfully by Tait, Mayo Robson, and others, and, in a limited number of cases, is safely and easily performed. But its frequent employment is of doubtful wisdom, since completeness of stone destruction can hardly be thus assured, and cholecystitis would be only a natural consequence of such manipulations.

When the gall-bladder must be incised, opinions differ as to whether it is wiser to open it at once, or to first sew it to the parietes, and open later, when adhesions will prevent escape of bile into the peritoneum. Riedel, von Winiwarter, Merkel, Levy, and others advocate the latter; Tait and a majority of operators, the former. The weight of reasoning seems against the operation *à deux temps*. For, in the first place, by sponges, gauze, etc., bile may be prevented from entering the peritoneum; and in the

next place, even should a little do so, no harm results. Hans Kehr[1] reports a case of pistol-ball wound of the gall-bladder flooding the abdomen with bile, without peritonitis. And Lane[2] relates another case in which, after injury, bile was poured into the peritoneum, and remained there harmlessly five weeks. It thus seems clear, as Kehr insists, that not bile, but strepto- and staphylococci are the causes of peritonitis. But, as the character of the bladder contents cannot be known beforehand, precautions are always to be taken against their escape.

The controlling objection to the *Zweizeitige Operation* is the fact that one is unable to thoroughly examine for calculus impacted in the ducts. A stone is frequently to be located only by a sound inside and a finger outside the gall-bladder, and to be removed only after incision of the duct. Dr. B. F. Curtis[3] relates a case where, on opening the gall-bladder after it had become adherent to the parietes, he found the cystic duct blocked by impacted stones. He was obliged to make a second opening in the middle line to admit his finger, between which and an instrument in the gall-bladder he could crush the stones. A calculus encysted in the gall-bladder can scarcely be removed without a supporting finger outside. Very vividly, Riedel, the most prominent advocate of the operation in two stages, relates the difficulties he has met in extracting stones from the ducts and from sacculi, after the bladder had become adherent to the parietes.

It is to avoid such embarrassments that most operators open the gall-bladder immediately. When fluid is present, it is aspirated, and the flaccid bladder-wall is grasped by catch-forceps, drawn forward, and after sterilized gauze has been packed about its sides, it is opened, and the contents removed. Search is then made of the ducts. If a stone be found there, it is pushed back into the bladder, or forward into the intestine; or, this failing, it is crushed, or removed through an incision in the duct.

All this may be simple and easy; or, when adhesions are strong and bleed fast, when the gall-bladder is so shrivelled as to be invisible and nearly indistinguishable by touch, when masses of exudate exist so thick and hard as to simulate cancer, or so involved as to require long unravelling, the operation strikes the surgeon as extremely difficult.

Cholelithotomy may be completed in two ways:

1. The incision in the gall-bladder may be sewn by Lembert sutures, the viscus dropped, and the external wound closed. This operation, which avoids an external biliary fistula, and places the patient in the same state anatomically as if he had not been operated on at all, has been ennobled by the title "Ideal Cholecystotomy." A healthy gall-bladder and the full permeability of the ducts are essential to its success—two points hard to determine. It may, firstly, be difficult to decide whether catarrh of the gall-bladder is present; and especially to foretell whether the operation, with its probings by fingers and instruments, may not be followed by a reactive inflammation, in which case the bladder will become distended and the result endangered. Parkes[4] emphasizes the likelihood of increased muco-biliary secretion after operation, and advocates a temporary fistula as a safety-valve. Whenever it is decided to do the "ideal" cholecystotomy, it will be wise to leave in the abdominal wound a good-sized drain leading to the sutured cut in the gall-bladder, as an escape for fluids in case of rupture.

The permeability of the ducts is also difficult to determine. Unless they have been dilated by calculi, it is rarely possible to catheterize them. Ferrier and Dally[5] could pass a sound only five times in twenty cadavers. Abbe[6] has sought to ascertain this essential point by ligating a syringe in the gall-bladder and injecting Thiersch's fluid through the ducts—a clever method likely to be of great use.

"Ideal cholecystotomy" is open to the further objection that incarcerated or encysted calculi may not be discoverable at the time of operation, and so are shut in beyond escape, whereas they may find exit later, if a way be left open. Dr. Arthur Cabot[1] reports a case in which, six weeks after operation, thirty stones discharged that had presumably lain in some extra-cystic cavity, whose contraction had carried them back into the bladder again.

The field of "ideal cholecystotomy" seems, therefore, limited. A majority of operators rely on:

2d, The classical cholecystotomy of Tait. Here the wound of the gall-bladder is not closed, but it is sutured to the abdominal wound, preferably not to the skin, but to the peritoneum and transverse fascia, in order to avoid a too-protracted fistula. If, owing to the shrunken state of the gall-bladder, this is impracticable, then glass or rubber tubing, perhaps surrounded by gauze tamponade, is placed against the bladder wound. Riedel[2] has proposed to utilize the parietal peritoneum in such cases, turning and suturing it so as to form a gutter through which discharges reach the surface; and Lauenstein[2] suggests using the great omentum for the same purpose. Openings made in the ducts are closed, or, if this is impossible or inexpedient, are drained. Abbe's plan of inserting into the duct wound a rubber tube, which passes through a glass one, and which may be removed later, leaving the glass in place, is worth remembering in this connection.

A fistula remains which commonly closes spontaneously. Ten years ago much was made of the damage to health by long-continued loss of bile. But experience of many cases of biliary fistula and improving health, has led to the belief that bile is mainly excrementitious. Fistulæ are a nuisance, but nothing worse.

To do away with this unpleasant sequel, substitutes for cholecystotomy have been proposed. Cholecystectomy, or complete removal of the gall-bladder, is one of these. It has been practised and recommended by Langenbuch and others. But its greater difficulty, its usual needlessness, and its higher mortality, have led to its being reserved for cases of malignant disease of the gall-bladder, or for organic occlusion of the cystic duct. It has also been employed by bold operators to rid patients of fistulæ after cholecystotomy.

In cases of impermeable *ductus communis choledochus*, an anastomosis between the gall-bladder and the intestine has been established. Thus bile which is dammed back into the bladder reaches its normal destination, the intestinal canal, and no external fistula remains. Cholecystenterostomy was suggested by Nussbaum, in 1880, and first practised by von Winiwarter in 1882. The anastomosis may be made by attaching the gut and gall-bladder by Lembert sutures. Murphy[4] uses his "buttons" for this purpose, and claims great ease and safety of performance. The connection may be made with any part of the intestinal tract, the hepatic flexure of the colon as well as the small intestine. This operation has proved very useful in closing intractable biliary fistula, and for this purpose seems preferable to cholecystectomy.

Other procedures have occurred to inventive operators. Sprengel[5] has made an anastomosis between an enormously distended duct and the intestine, and terms it choledicho-duodenostomy. And Tielewicz[5] has simply ligated and severed the cystic duct, thus retiring the gall-bladder from active duty, and leaving a mucous fistula, which, he assumes, will close spontaneously.

In reading something of the literature of gall-bladder surgery, I have observed that most practical help came to me from clinical histories detailing difficulties and means of meeting them. Let me, then, offer the history of two cases of my own.

The first was a woman about fifty years of age, whom I saw in consultation with Dr. Sheldon Voorhees. For ten

years she had been a martyr to biliary colic and jaundice. The attacks had become more and more frequent and severe, jaundice was nearly constant, and the most of her time was spent in bed. Calculi had been searched for in the stools without success. No tumor could be felt. After consideration she decided to accept relief from surgery, and was admitted to the Auburn City Hospital.

On January 16, 1893, cholecystotomy was done under strict asepsis. The incision was made an inch or so from, and parallel to, the costal cartilages. A distended gall-bladder at once presented in the wound, and about one-half pint of dark gall was aspirated. The bladder, held by catch forceps and well enclosed by gauze, was then opened. Some little bile escaped into the peritoneal cavity. The most careful search failed to discover a stone in either the bladder or the ducts. This is not so very unusual. In several operations which I have witnessed in this country and abroad, no stones were found, and many such cases are reported in the journals. It may be that the last stone had been passed just before the operation; or, what seems more probable, that stones were originally present, and set up a cholecystitis. After the stones escape, the catarrh persists, and the bladder remains chronically distended, partly emptying itself at intervals of inspissated bile and mucus, with the phenomena of biliary colic.

The edges of the bladder wound were now sewed to the skin in the middle of the parietal incision, the rest of which was closed with silk-worm-gut, except where a glass drain entered, a precaution taken in view of the escape of bile before spoken of. A rubber drain was placed in the gall-bladder.

The patient did perfectly well till the third day, when she unexpectedly developed acute dysentery. Collapse on the fifth day. The disease then came slowly under control. All this while the wound did well.

With the exception of this intercurrent trouble, recovery was uninterrupted. When I last saw her, five months after operation, she expressed herself as better than in years, and had just completed her house-cleaning.

The second case was that of a woman, twenty-one years of age, married, one child a year old. Since its birth she has had attacks of biliary colic about every four weeks. The frequency of the attacks kept her in bed a good share of the time. No stones had been found in the passages, and no tumor could be detected in the abdomen. The case seemed not one of severe type, but when the patient learned that relief was obtainable by operation, she decided, after undergoing two further sieges, to enter the hospital. On admission, jaundice had disappeared, but there was tenderness over the gall-bladder, and some fever, which fell gradually.

On May 23, 1893, the abdomen was opened by the oblique incision. Gall-bladder not noticeably distended, and stones plainly felt in it. It was isolated by gauze and opened, and a half-dozen small calculi removed. One stone was squeezed from the cystic duct back into the gall bladder. The bladder opening was then sewn to the abdominal wound, and this closed. No shock, but vomiting and pain. By an oversight no rubber drain had been placed in the bladder, and on the third day its opening was found clogged with clots. On removing them and inserting a tube, free flow of bile followed, with relief to distress. A good-sized stone was washed out of the bladder on the fourteenth day. The wound was healed, when in the third week the patient developed an appendicitis which, for twenty-four hours, threatened to make her again a subject for operation, but finally subsided.

This case has interest from the fact that the pain was so torturing as to lead the patient to elect a dangerous operation as a means of relief, yet the calculi were small, and the gall-bladder healthy.

In concluding, I cannot do better than quote Ignatow's summing up, based on two hundred and seventy-eight tabulated cases:

With intense pain and evidences of duct obstruction, operate.

Ordinary cholecystotomy is the typical operation and gives lowest mortality.

"Ideal cholecystotomy" may be used in fresh cases with little change of the gall-bladder.

This and cholecystectomy have given about an equal mortality.

Cholecystectomy should be limited to malignant disease of the gall-bladder and impermeable cystic duct.

Cholecystenterostomy is advisable in occlusion of the ductus choledochus.

A CASE OF CONVERGENT SQUINT, WITH REMARKS.

By HOWARD F. HANSELL, M.D.,

PHILADELPHIA, PA.

July, 1891.—Eva B——, aged six, has had internal squint since she was four years old. There has been no noticeable increase or decrease in degree from that time. The right is the fixing eye, while the left is markedly deflected inward and apparently maintains a constant degree of deviation toward the axis of the right for all distances. When the right is covered the squint is manifested in the left, but fixation with the left is relaxed as soon as the retina of the right is allowed to functionate. The refraction was determined by retinoscopy and with the ophthalmoscope: R. $+ 2 = \frac{6}{8}$; L. $+ 2.50 = \frac{6}{18}$. The acuity of vision could not be satisfactorily obtained on account of the youth of the patient, and full correction was ordered—tenotomy of the internal recti under ether. For the remaining few days that the child was under observation the squint seemed to have been entirely cured.

April, 1893.—During the interval of nearly two years she has constantly worn her glasses. She now returns according to instructions. The squint has reappeared. The above refraction is modified by the addition of weak convex cylinders, and better vision is obtained (R. $\frac{6}{6}$; L. $\frac{6}{12}$). I again performed a double tenotomy, this time under cocaine, and with a perfect result, as in previous instance, apparently. A few days later the left was again deflected. Two failures in the same case! After several tedious examinations I was able, by means of a red and a dark blue glass, to compel Eva to acknowledge the true and false image of a candle-flame at 6 m., homonymous, and on different horizontal planes —esotropia 10°; R. hyperphoria, 4°. The right superior and left inferior recti were divided until vertical equilibrium was restored. The convergent squint was immediately replaced by a divergent squint equal to 10°.

This is a brief recital of the salient points of a case which is fairly illustrative of a most common affection, and furnishes food for reflection—unpalatable when one remembers the useless operations performed, but withal necessary for those yet to come.

Several practical questions suggest themselves.

1. Is hypermetropia the sole cause of functional internal squint?

We have accepted, and blindly, until Stevens, in his admirable and eminently practical series of articles in the "Archives of Ophthalmology," on the "Anomalies of the Ocular Muscles," opened our eyes, the explanation of Donders, that concomitant internal squint arises through excessive stimulation of the internal recti, which is a necessary consequence of the extraordinary contraction of the accommodation required to overcome hypermetropia in the attainment of good acuity of vision, and that it can be cured by correction of the optical defect only, or by tenotomy in addition to the lenses. Experience teaches us that this is sound doctrine only in a certain proportion of cases; such, for example, as those in which the squint disappears while the accommodation is paralyzed during sleep, deep narcosis, after death, or where the squint appears only while working at the near point. That the above case does not belong to this category is

evidenced by its course; it persisted under complete suspension of accommodation by atropine, and during its limitation to the normal degree of activity by the constant wearing of a full correction, nor did tenotomy of the interni, twice performed, bring about permanent improvement.

2. Is convergent squint due to a preponderance of function of the interni muscles because the muscles themselves are hypertrophied, and the normal relation between them and the externi disturbed, or are the externi abnormally weak?

That such causes are operative is well known. In long-continued squints where the vision of one eye is weakened or destroyed, either by congenital defect or accident, that eye is converged or diverged, and the contracted muscle is larger, thicker, better nourished—its antagonist thinner, pale, and wasted. But such cases do not belong to a discussion of purely functional squint. In this case the sudden appearance of divergence, in the place of a hitherto incurable convergence, upon the restoration of vertical equilibrium, shows conclusively that the previous convergence was certainly not due to an anatomical preponderance of strength of the interni, nor to inherent weakness of the externi. Moreover, the length of time the squint had been noticed previous to the first operation was too short for an atrophic process to be effective.

3. Is amblyopia an important factor in the causation of squint?

Amblyopia means in this connection dull or blunted vision without evident pathological changes, and must be discriminated from loss of vision from disease. Again, the line must be drawn between the amblyopia which can be improved by hypermetropic or astigmatic correction, which is not amblyopia at all, and that properly called amblyopia in which lenses not only do not improve but make no material difference.[1] The question might with equal fairness be transposed, thus: "Is squint an important factor in the causation of amblyopia?" so little do we know of the real nature of amblyopia. Hypermetropia, internal squint, and acquired monocular blindness may coexist. Case—boy, aged ten. R. no light perception; L. $\frac{6}{15}$ +; H. 4° in both (ophthalmoscope). Wide internal squint of right for five years. No paralysis, single or associated. There is no history of nervous disease, and the boy is well developed mentally and physically. Right, total atrophy of optic nerve and retina; left, a few small patches of chorio-retinal degeneration, nerve pale, and slightly concentrically contracted field. Very slight improvement followed double tenotomy. Or, hypermetropic and monocular acquired blindness are found without squint. Case—girl, aged eight. Right, total atrophy of optic nerve and retina; left, not involved. No history of convulsions or nervous disease. R. V. = 0; L. $\frac{6}{6}$. In both H. = 1.50. The cause in each case remains undiscovered.

Monocular congenital amblyopia is not invariably the cause of squint, even when associated with a moderate degree of hypermetropia. Case—G. C——, aged twenty-five. R. + 2.50 = $\frac{6}{6}$; L. $\frac{6}{6}$ + 2.50 by ophthalmoscopic measurement. No improvement in vision with any glass. No changes visible through the ophthalmoscope in either eye. Axes parallel.

In acquired amblyopia the visual axes may be convergent, parallel, or divergent. When convergent, the squint must be ascribed to coexisting hypermetropia and is independent of amblyopia, if parallel muscular equilibrium and equal innervation is a necessary condition; if divergent—the most common form—efforts at adduction have been relinquished and the eye is passively abducted, the direction of its axis conforming to the direction of the principal axis or the orbit. In convergent functional squint amblyopia is the rule, but it cannot logically be considered the cause or the result, neither can it be said that it is cured, even in the youngest children, by glasses or by tenotomy.

[1] Attention has been called to this subject by Dr. Gould in the Medical News of December 31, 1892.

4. Does convergent squint depend upon other muscular anomaly?

Permanent fusion or binocular fixation demands a condition approaching equilibrium of all the ocular muscles. Absolute equality of function of the acting and antagonistic muscles is rare, and stands in relation to muscular anomalies as emmetropia does to errors of refraction. When, however, the inequality of function of two opposing sets of muscles oversteps a certain limit, where the tendency becomes a reality, fusion can be maintained for a short time only, or not at all. The limit varies in different individuals, and in the same individual at different times, and depends upon the acuity of vision and refraction of each eye, and on the disposition of the patient, general health, and, perhaps, heredity. It may be stated approximately that in esophoria of 10° or more, exophoria of 8° or more, hyperphoria of 2° or more, diplopia may be elicited. The convergent squint in Eva's case was proven to depend upon a want of equilibrium of the vertical muscles. Association of hyperphoria and esophoria is, I believe, very common, but my experience has not hitherto included a case in which I could demonstrate conclusively and immediately that the esotropia depended upon hypertropia. The convergent squint resisted two double tenotomies, the wearing of a full correction for nearly two years, and disappeared only after vertical equilibrium was secured. Donders in his explanation of internal squint in hypertropia might have gone farther. The stimulation of the third pair of nerves induced by the extraordinary contraction of the ciliary muscle must involve a proportionate abnormal stimulation, and hence contraction of all the muscles of both eyes which are under the control of those nerves. Hence hypertropia may be the cause of a loss of vertical as well as of horizontal equilibrium, since it can be easily conceived from some anatomical difference in the strength of the muscles, higher error of refraction, or worse vision in one eye than in the other, that the superior rectus of one and the inferior rectus of the other may become more strongly contracted than their antagonists. Herein lies the true explanation of the unsatisfactory results of squint operations—neglect to investigate the conditions of the vertical muscles. It is within the experience of every ophthalmic surgeon to meet, not infrequently, cases of convergent squint that tenotomy had failed to cure, and cases of divergent squint which were the result of extensive division of the internal recti tendons. With scarcely a thought other than that the refraction must be corrected, the operator has followed the usual routine—atropia, glasses, tenotomy of one or both interni, and the patient dismissed. Indeed, a favorite reason for advocating the operation is that the squinting eye may be brought into line with its fellow, and the amblyopia which has arisen out of the neglect to use that eye in vision would be cured. The cure of the amblyopia is a myth, the result of the operation, excepting that comparatively few in which binocular single vision is obtained, doubtful.

To Stevens belongs the credit of insisting, in words that should be convincing, on the influence of unequal tension of the vertical muscles in the production of other muscular anomalies, and that the prevailing method of operating for the cure of internal squint is unscientific and ineffectual, and that the true explanation of the failures to give binocular fixation was not, as v. Graefe explained, "antipathy to single vision from faulty projection from the retinæ, and from the supposed difficulty of obtaining regular associated action between muscles which had long been unaccustomed to association," but that they depended upon "unequal tension of corresponding ocular muscles under the influence of corresponding nerve impulses directed to them." Stevens's doctrines have not yet received the full endorsement of the profession, but they are gradually securing a foothold, and will, doubtless, obtain the prominent place in the therapeutics of ophthalmic science that their merits warrant.

5. How shall convergent squint be treated?

The answer may be briefly stated. Let the patient ac-

knowledge diplopia, and the relation of the false to the true image will indicate the operations to be performed. If the images are on one horizontal plane—and the conclusion should not be reached after a single examination—unequal vertical tension does not exist. At first the patient will, unconsciously, refuse to see the image of the squinting eye; but if the image of the fixing eye be rendered indistinct by means of a dark-blue glass, for instance, a little perseverance, patience, and encouragement on the part of the examiner will invariably be rewarded by the patient confessing diplopia. If vertical deviation is discovered, the two lights should be brought to a horizontal plane by tenotomy of the appropriate muscles before operations on the interni are attempted. I have made Eva's case simply a text for my remarks, and other cases, not reported, have shown me the justice of Stevens's claims, and my experience has determined me in the future to observe the following precautions or rules in operating in cases of functional convergent squint.

1. To postpone operations until the patient is old enough to recognize double images of the candle-flame at 6 m., and to accurately describe their relative positions.

2. If vertical deviation of more than 2° is shown, tenotomy of the superior or inferior rectus, or both, should be the first operative procedure.

3. Careful tenotomy of both interni should follow as the second step. An operation on one internal rectus, designed to correct manifest convergent squint, is unscientific in that the physiological balance between the divided muscle and its opponent will be permanently destroyed, rotation inward of that eye will become limited, and divergence may ensue.

254 South Sixteenth Street.

ON THE INTERNAL ADMINISTRATION OF CALOMEL IN THE TREATMENT OF PSEUDO MEMBRANOUS LARYNGITIS.[1]

By S. KOHN, M.D.,
NEW YORK.

Any fixed and definite method, which promises only a modicum of success, in the treatment of membranous croup, must command the respectful attention of every practising physician; in no other acute disease of childhood is the mortality so great; in no other does the hopelessness of the physician's efforts seem so manifest.

The numberless methods of treatment of this disease attest the industry with which physicians have striven to overcome the gradually increasing laryngeal stenosis which has been regarded as its greatest danger.

Venesection, veratrum viride, antimony, the emetics, vegetable and mineral, nitrate of silver solutions (ten to sixty per cent.) locally (Bretonneau and Green), medicated steam inhalations, and numberless drugs newly invented and older ones, have had their warm supporters, who have claimed for their methods a certain percentage of recoveries without operation.

Taking the consensus of opinion of recent years, the most widely popular drug in the treatment has been mercury, in the form of corrosive sublimate, in large doses, with or without the muriated tincture of iron and chlorate of potash; still more recently inunctions with blue ointment have been recommended in the treatment of laryngeal and faucial diphtheria.

It may seem superfluous to mention these different methods, but the object is to show that, after all the varying phases of treatment which an historical survey of the literature reveals, mercury to-day is essentially the drug upon which most reliance is placed by the majority of medical men.

Before speaking of the treatment by hourly doses of calomel, which will be recommended in this paper, the writer would direct attention to the characteristic clinical features of the disease in their relation to the treatment. A child, with or without discernible diphtheritic processes in the pharynx, exhibits the signs and symptoms of so-called "true croup," or laryngeal diphtheria, viz., a low, rasping inspiration; dry, brassy cough; retraction of the soft parts of the chest on inspiration; hoarseness; fever. Each symptom in this complex gradually increases in intensity; the inspiratory stridor becomes louder; expiration also becomes noisy and prolonged; the breathing meanwhile grows rapid, assuming the characteristic sawing sound; cough is more metallic and drier; the retractions become extreme; the hoarseness gives place to aphonia; cyanosis appears. The two factors productive of this condition are the closely adherent diphtheritic membrane and the inflammatory swelling of the mucous membrane and submucous tissue of the larynx.

The membrane, starting at one point, say the posterior surface of the epiglottis, extends to the upper surface of the vocal chords, invades the ventricles of Morgagni, passes on to the vocal bands, and may extend into the trachea and bronchi of smallest calibre; the glottic aperture is slowly encroached upon, until complete closure occurs and death from suffocation ensues; or croupous plugs in the bronchi and broncheoli may so limit the lung capacity that the patient succumbs. This growth of the membrane produces, in addition to the disturbances in the respiratory organs, a gradually increasing carbonic-acid intoxication and infection of the organism.

The growth of the membrane may, on the other hand, be self-limited; and when complete occlusion of the glottis seems imminent, a change in the character of the breathing is noticed; instead of the dry, sawing sound, a moist, fine râle is heard in the larynx; the metallic cough becomes moister, softer; the retractions of the soft parts of the chest become less marked; the aphonia gives place to hoarseness. The membrane having ceased to extend, has become disintegrated, soft; suppuration has separated it from the underlying mucous membrane, it has been expelled by the cough, either piecemeal or *in toto*, and slowly but surely a "restitutio ad integrum" occurs in the larynx.

The remedy, which experience has shown to have the effect on the membrane of liquefying or softening it, is therefore the great desideratum; medicated steam inhalations (lactic acid, lime-water, turpentine), and sublimed calomel (Dillon Brown) have been given with this object in view.

Calomel administered internally, in the manner to be hereafter described, has, in my experience, seemed to have this effect; and the results have been so satisfactory, that this method of treatment seems to me worthy of the highest commendation.

To a child under two and a half years, 0.05 of pure calomel is given hourly, sleeping and waking; for each year above two and a half years, add 0.02 of calomel to the hourly dose. A child of five years would therefore take 0.01 of calomel every hour. The calomel must be absolutely pure and undeteriorated; it should be given without the admixture of sugar of milk or of any sugar whatever; it may be administered, either floating on a teaspoonful of water, or if the child refuses this, because he knows it to be medicine, it may be given in milk, entirely unnoticed by the patient.

The case should be under the watchful care of a trained nurse, who must keep an accurate record, noting the slightest perceptible change in any of the characteristic signs; after one or two grammes of calomel have been given, a change in the laryngeal breathing sound should be noticed. The treatment should, and can, be instituted at the earliest possible moment after the diagnosis is made.

The writer has given a child of two and a half years, 0.06 of calomel hourly, until four grammes were taken; the patient recovered. To another child of three and a half years, five grammes were given with success. A stimulating and supporting regimen to combat the sepsis was adhered to—beef soup, white of egg, milk; Tokay wine, or whiskey, were administered alternately, at very frequent intervals.

[1] Read before the Metropolitan Medical Association, May 24, 1893.

The administration of nourishment and stimulants, half-hourly, to sustain the heart power, is of the highest importance; everything given the little patient should be palatable and easily taken, as every struggle of the child against taking food or medicine increases the laryngeal stridor, and perhaps causes the membrane to extend downward.

The use of mercury in plastic inflammations is one of the traditions of medicine; its praises have been sung by medical writers for more than a hundred years; whether its so-called antiphlogistic properties are explicable by reason of its destructiveness of germ-life, it is not for me to say. The action of calomel in croup, given as above described, bears out the old belief, in actual experience. Under its use I have seen the stridor, the aphonia, the cough, in short all the symptoms, slowly abate, showing that the membrane was gradually loosening its hold and becoming innocuous.

The advantages of calomel over sublimate are self-evident; the former is mild, non-irritating, can be taken for the necessary length of time without any other effect than a passing diarrhœa, perhaps; while the sublimate is a pronounced irritant poison which, taken in frequent doses, will cause pronounced gastro-intestinal irritation, necessitating an interruption in the treatment at a critical period.

The powder of calomel of six centigrammes is small, tasteless, and easily administered to the most obstreperous child; not so with the bichloride mixture, when given hourly. If inunctions with blue ointment have been attended by the success claimed for them in diphtheria, then mercury *absorbed into the circulation* seems to have a controlling influence over the diphtheritic infection, and its local manifestations.

For administration to children, calomel must be preferred to all other preparations of mercury, for reasons that are obvious. The danger of salivation, in my experience, is minimal; I haven't seen a case of ptyalism among the children that I have treated with calomel.

Severe diarrhœa has also been very rare. Three, four, or even five movements a day under the calomel therapy I should consider rather an advantage in this disease, provided the patient take nourishment; the sepsis is, to a certain degree, mitigated by the free action of the bowels.

Should the diarrhœa assume a severe or alarming character, the dose of calomel may be diminished, or the intervals between doses prolonged; or a starch injection, with or without a little paregoric, may be given; and if the laryngeal obstruction seems to be lessening, I would not stop the calomel altogether under any circumstances.

A very strong argument, from a pathological standpoint, in favor of the antiplastic treatment by calomel, or by mercury in any form, is found in the statistics and post-mortem examinations of Prudden and Northrup.[1] In 151 fatal cases, pneumonia was found in 104. In Northrup's article in Keating[2], in 87 cases, the larynx alone was affected in only one case; in another the membrane extended from the pharynx to the middle of the trachea; between this point and the bronchi of the fourth division nothing was to be found; from these to the finest bronchi, membrane was present; in 34 cases the membrane extended from the pharynx down to the finest bronchi. In view of this extensive growth of membrane, of what use can an inhalation be? The tidal air, which alone can carry the inhaled medicament, never reaches the finest bronchi; of what use, therefore, is any local treatment? The treatment by sublimed calomel (Dillon Brown) seems to me to be the treatment which is advocated in this paper, but in a different form. It formerly was one of the methods of mercurializing a patient, to volatilize calomel on a metal plate by means of an alcohol lamp. The treatment has the disadvantage of salivating the attendants of the child.

In mercury we have a drug, then, which, absorbed into the circulation, would seem to have a specific effect on the membranous exudation of laryngeal diphtheria; and of all its preparations, the mild chloride for administration to children is the best for easily bringing the system rapidly under its influence.

It is not claimed that recovery occurs in every case, nor am I in a position to bolster up assertions by statistics; favorable statistics would be accepted with incredulity, anyway.

The object of this paper is simply to direct your attention to a specific and definite method of treatment, which, from inquiry, I am convinced is not at all in use among physicians in this city, and which in my practice has proven eminently gratifying in a number of cases; which, if followed to the letter, will fully meet your expectations. Its simplicity, ease of application, the fact that treatment can be instituted the moment laryngeal stridor is noticed, in even the youngest child, are arguments in its favor.

Should the patient go from bad to worse, in spite of the treatment, and the symptoms assume a grave character, recourse can always be had to intubation or tracheotomy; and here I would say, although it has nothing directly in common with my subject, that early operation is to be decidedly discountenanced, be it intubation or tracheotomy. In either case a new danger is added which, in my opinion, may have been, in some cases of early operation, the cause of death.

Recovery from diphtheria of the larynx is undoubtedly possible without an operation, and the child's chance of life should not be jeopardized at the outset of the disease, to satisfy the theory of "early operation." The writer has tracheotomized children apparently at the last gasp, and has saved the life of the patient by the operation. Operation should be the *dernier ressort*. The chance of success in my experience has been just as great in late as in early operations.

A few brief histories may be of interest. In the fall of 1887, Dr. Arnim Fischer called me in consultation to see a baby, two and a half years of age, who had all the symptoms and signs of diphtheritic croup. Two children in the same family had succumbed to the disease a few days previously; the elder, aged six years, had been tracheotomized; the younger, aged four years, had been intubated by other physicians. When the third and youngest child was taken sick the parents determined to have no operation performed. I advised the attending physician to give pure calomel in doses of 0.06 hourly. A slight amelioration of all symptoms was noted after 1.0 had been given. The child recovered, having received 4.0 of calomel in all.

Another case, seen by Dr. A. Jacobi in consultation late at night, was that of a boy, three years of age, who had gray patches on both tonsils, marked sawing stridor in the larynx, with inspiration and expiration. Dr. Jacobi thought intubation indicated. The parents, when I had explained to them the dangers of the disease with and without operation, decided to wait and consented to a trial of the internal treatment. The calomel was given in hourly doses of 0.1. The stridor was slowly overcome, the dry sawing sound in the larynx gave place to the moist flapping of the loosening membrane, expectoration became copious, purulent, and the patient recovered. This patient took 6.0 of calomel in all.

I might relate case after case in which the calomel has not disappointed my expectations, in the treatment of croup, but it would not strengthen the assertions already made in this paper. These cases have been recorded for the purpose of showing how large a quantity of calomel can be taken in divided doses by young children, with impunity. No urgent signs of mercurialism occurred in any of my cases, which would have necessitated a discontinuance of the treatment, nor can I say that I noticed any bad after-effects. It is an argument against all treatment by mercurials, that their deleterious effects on the blood and tissues remain long after the disease for which they are given is past; in my opinion, a drug that prom-

[1] American Journal of the Medical Sciences, June, 1889.
[2] Cyclopædia of Diseases of Children, 1889.

ises to rescue a child from the terrible agony of death by suffocation may be given, even at the risk of incurring bad after-effects; there is ample time to treat these later and to get rid of them, but the suffocative attacks of laryngeal diphtheria don't allow much time for the consideration of after effects. The writer considers steam inhalations, in any form, an important adjunct to the treatment.

To sum up, the claims for consideration of this drug, in the treatment of laryngeal diphtheria, are based on the following grounds:

1. Mercury is to-day the one drug upon which most reliance is placed by the medical profession in the treatment of diphtheria; and from the various ways in which it is used with benefit, it probably exercises its good effect through absorption into the circulation

2. In the experience of the writer the hourly administration of 0.05 of calomel has had, in many cases, the satisfactory result of softening and liquefying the diphtheritic membrane, and of avoiding the necessity for operation.

3. The ease of administration to children, and the absence of irritation in the gastro-intestinal tract.

In closing, the writer must state that, though this method of treatment is the result of his own thought and experiment, he does not and cannot lay claim to originality, inasmuch as Dr. W. H. Daly, of Pittsburg, in a paper read before the American Laryngological Association in 1886, advocates the same treatment with great enthusiasm. Dr. Daly's paper is very brief, and in reality is simply a statement of his belief in this therapy. He, in turn, makes the admission that he is indebted for his knowledge of this method to Dr. William C. Reiter, who, in 1878, directed attention to it in a monograph "On the Treatment of Diphtheria, Based upon a New Etiology and Pathology;" nor is this the first time that the treatment was given publicity. Sidney Smith, the noted divine and essayist, by the advice of his physician, treated his grandchild for a disease which must have been, from the description, diphtheritic croup, by hourly doses of calomel, and saved its life. In gratitude to the physician he published the method to the world.

BUFALINI'S CAMPHORATED CARBOLIC ACID AS AN ANTISEPTIC AGENT.

By S. W. S. TOMS, Ph.G., M.D.,

BELLPORT, L. I., N. Y.

LATE HOUSE-SURGEON, BUFFALO GENERAL HOSPITAL.

It is very interesting to learn that that eminent surgeon —"the father of antiseptic surgery"—Sir Joseph Lister, has recently announced that he has returned to his first love—carbolic acid. After these many years since his first employment of it for a definite purpose of prophylaxis against the entrance of germs to fresh wounds, and for antiseptic and germicidal purposes—the birth of the "antiseptic" idea and theory—after these years of painstaking clinical experiment and bacteriological research, it is at least remarkable that the first antiseptic, used as such, should now hold the first place in the favor of so careful an experimenter and observer as Lister. All those chemical agents which have enjoyed more or less confidence in their efficiency with authorities in surgery as "antiseptics," seem, after thorough testing of their merits, to have been found wanting. To be sure the "antiseptic" theory has largely been supplanted by "aseptic" principles—the natural evolution of the primary conception of the author—but there are many surgeons who, still having much confidence in carbolic acid, find yet very many and grave objections to its employment in a general way in surgical work, especially in private practice.

Its field of usefulness, although acknowledged by its most ardent employers to be perhaps greater than that of any other permanent and staple compound combining the essential antiseptic properties, would be still greater were it not for toxicity, odor, caustic action, etc. Its employment as a germicide, in strength sufficient to be effective against pyogenic bacteria and their spores, is fraught frequently with considerable danger, and often in an infected wound is not at all possible excepting by a long and continued use in much reduced strength, in which nature plays the most important *rôle*, owing to its destructive properties to living tissue. As an antiseptic protective against the entrance of bacteria infecting a sterile wound, through the dressings, it is questionable if it does not materially impair the integrity of healthy structures rather than act kindly in promoting the process of repair.

Recently I had occasion to resort to other means than the regulation dry dressings with dusting powders—iodoform, aristol, dermatol, etc.—in treating an extensive ulcerating epithelioma whose surface covered about 600 sq. ctm. of the leg. Amputation was out of the question owing to the debility and age of the patient.

The odor, amounting to stench, the extreme irritability of the wound from exposed nerve-filaments, the deep points of ulceration, extensive absorbing surface, together with the profuse discharge, made up a condition that put my ingenuity to test. After employing "them all," together with antiseptic absorbent dressings, and almost despairing of ameliorating the sufferings of my patient, or mitigating the condition in his home, my mind reverted to Lister's first choice and last resort—carbolic acid—in the hope that perhaps it could be utilized in some form to meet the indications in so appalling a case. Certainly carbolic acid possessed the ideal properties, *i.e.*, antiseptic, deodorant, and anæsthetic, but its offensiveness was only second to that of the wound; besides, it would be required to employ it strong enough to check suppuration, in which strength it would be caustic or certainly irritating, while the extent of surface gave reason to fear possible absorption and development of toxic symptoms from prolonged use of the drug. Remembering that I had become acquainted, while engaged in the drug business, with a proprietary preparation which claims to be a fifty per cent. solution of pure carbolic acid combined with camphor, and is stated by its manufacturers to be non-irritating, the caustic properties of the acid being destroyed, I concluded to try this on the wound of my patient.

Instead of using the proprietary article I had my pharmacist make a small quantity after the formula of Bufalini, as given in the United States Dispensatory,[1] to see in what way it differed from the secret article. I found no difference in the appearance of the two preparations whatever, excepting that the one I had made in full strength was not irritating to the mucous membranes of the mouth, while the proprietary article was. I also had it made in the fifty per cent. combination, which differs only in strength from Bufalini's formula, and this was not found irritating to mucous surfaces. It is stated in the Dispensatory that this preparation retains the full antiseptic and germicidal properties of the acid without its destructive action to living tissue.

Although I have not made laboratory experiments to demonstrate the claims of its originator, yet clinically I believe it to be so. In the case I have mentioned I diluted it with fifty per cent. of cotton-seed oil, applying it directly to the ulcer and covering it with sheet cotton saturated with the same; over this was spread a dry antiseptic absorbing pad made of powdered charcoal and antiseptic wood wool, about half an inch thick, spread evenly between cheese-cloth gauze.

For cleansing purposes an irrigating solution was employed, composed of 1 to 1,500 bichloride mercury, combined with 3 to 1,000 sulphate of copper,[2] which I have found more effectual than the bichloride alone. After the accumulated secretions are fully washed away, the surface is sprayed with 15 volume peroxide of hydrogen, after

[1] United States Dispensatory, 16th edition, pp. 53 (Wood, Remington, and Sadler).

[2] Suggested by Mr. R. H. Meade, U.S.

which the application is made as described. I have been using this now for about three months in this case, with the happiest results—perfect deodorization of the wound and lessening the formation of pus.

The patient is markedly more comfortable, the irritation has been allayed by the antiseptic and local anæsthetic properties of the remedy, and the extensive breaking down of tissue has been materially checked. Only one dressing is used in twenty-four hours, yet his freedom from pain enables him to comfortably sleep throughout the night, dispensing with the use of morphia, which he had been in the habit of taking, and requiring as a substitute a mixture of bromide, chloral, and hyoscyamus, in very moderate amounts. Moreover, the household are not continually nauseated by the all-pervading odor of the offensive discharges permeating the entire house. I have also employed this valuable antiseptic in recently lacerated wounds, and found, in every case, healing promoted under one dressing by primary union.

A nice drain can be made by dipping sterilized candle-wicking into camphorated phenol. It is far superior to all forms of dusting powders in the fact that it is not decomposed by contact with the serum-albumin and liberating irritating elements to fresh wound surfaces, as in the case of the iodine derivatives. It keeps the wound moist, is absolutely unirritating—on the contrary, is anæsthetic—promoting the process of healing in the most kindly manner, and is the best protection against the entrance of bacteria I believe we have. For this reason it is used to cover celiotomy and other wounds where union by first intention is so desirable. Nor do I believe its field of usefulness is confined to that of surgery alone, for it has positive therapeutical properties in dermatology. So much am I convinced of its merits and advantages over many other much-employed antiseptic agents that I deem it worthy of report and of further trial by the vast number of eminent surgeons who are still employing iodoform, etc.

Now that carbolic acid has been adjudged by its first exponent to be the best antiseptic, the knowledge of extending its sphere of usefulness should be widely disseminated.

SYPHILIS OF THE AUDITORY CANAL, WITH REPORT OF A CASE.

By G. MILTON LINTHICUM, A.B., M.D.,

BALTIMORE, MD.

ASSISTANT IN THE EYE AND EAR DEPARTMENT OF THE CITY HOSPITAL DISPENSARY.

The following case was seen in the service of Dr. Harry Friedenwald: C. W——, colored, aged twenty-five, of general physical and constitutional debility, was seen for the first time during January, 1892. His history was as follows: Before Christmas an otorrhœa appeared which for a time was painless, but at the end of about one week the auditory canals became exceedingly sensitive and sore. The walls of the canals when examined were found covered with small granulations, which so blocked them as to prevent a thorough inspection of their depths. There was also a small fistula behind the left ear.

The diagnosis was at this time made as suppurative otitis media, with the production of an eczema and granulations in the canals. The case was treated accordingly in the usual manner, by syringing and by the use of topical applications; this treatment was not attended by any improvement whatever, and during the whole time the patient complained of great pain in both ears.

Subsequently (about January 20, 1892) a more careful examination was made. It was then found that granulations covered only the walls of the outer half of the canal. These granulations were very sensitive and bled very readily on manipulation. There was also a marked tendency to deep ulceration of the walls. It at once became evident that this was not a case of ordinary middle-ear disease. The granulations were strongly suggestive of soft papillary syphilides, which led to an inquiry into the patient's history, eliciting the fact that he had had a chancre on the penis and enlarged inguinal glands of the right groin, several (?) weeks before the ear trouble was noticed; these lesions had disappeared subsequently. A large margin must be left as to the time of the appearance of the local lesion, as the patient was very ignorant. After consideration of this history, the diagnosis of secondary syphilis of the external auditory canal was made. Professor G. H. Rohé saw the case at this time and concurred in the diagnosis.

The treatment was now changed to the anti-syphilitic, *e.g.*, inunctions of mercurial ointment, and insufflations of calomel. Improvement was apparent from day to day. On January 29, 1892, the canals had lost their papillary appearance and presented smooth, clean surfaces, except at the orifices, and in the fossa between the tragus and ante-tragus of one side, where there was a broad, smooth, and moderately deep ulceration, but these ulcers were improving; under continuance of the mercurial inunctions and calomel insufflations healing steadily progressed. The last visit and examination was made on February 22, 1892; both tympanic membranes were normal, the ulcers had healed, and the walls of the canals were healthy, but the tragus of the right side was partly lost.

The rapid cure under the anti-syphilitic remedies permits of no doubt as to the correctness of the diagnosis. In this case the proper diagnosis was not made immediately; but others have fallen into the same error.[1] It therefore becomes important to study this malady carefully, and to learn the characteristic features by which it may be recognized.

Syphilis of the external ear may occur as a primary, secondary, or tertiary affection; it is to the second that this paper is chiefly devoted, though several cases of the former may be mentioned, as reported by Politzer.[2] The first two are mentioned in Lang's lecture "Upon the Pathology and Therapeutics of Syphilis (Wiesbaden, 1885). In one case the true Hunterian chancre was located on the lobe of the left ear, in the other the chancre was on the anterior wall of the canal. The first was infected by using a handkerchief of a syphilitic son, the second by the endearments of a prostitute. A third case is cited, where infection took place from the bite of a syphilitic during a fight.

Secondary syphilis of the auditory canal is, as shown by statistics, a very rare malady.[3] Desprès found, among twelve hundred syphilitics, nine hundred and eighty infected with condylomata, but of these only five had syphilis of the auditory canal. Out of four thousand patients Buck[4] diagnosed thirty as syphilitic, five of whom had ulcers and condylomata of the canals. Ravogli,[5] in one hundred and forty-four syphilitics, found fifteen with middle-ear affections, and only one with lesions of the outer canals. Condylomata of the auditory canal present the same feature as in other parts of the body where they are under the influence of moisture. They form excrescences made up of many wart-like elevations, often red or pinkish in color, usually extremely sensitive, and they bleed very easily on manipulation. The canal is not infrequently rendered almost impervious by the swelling of the walls. Unless treatment is instituted early, the condylomata break down with the formation of an ill-smelling discharge, later ulcerations are formed rendering the canal so sore as to often make the movements of the jaw painful. These ulcers may destroy large areas of tissue unless healing is promoted early.

The diagnosis is comparatively easy if care is taken to examine into the patient's history, but this is more often neglected, owing to the rarity of the affection. The usual history of syphilis, *e.g.*, a local lesion some time previous, with subsequent loss of hair, enlarged glands, and

[1] Wurdemann: Archiv Otology, vol. xxi., p. 303.
[2] Politzer: Ohrenheilkunde, p. 163.
[3] Desprès: Ann. des mal. de l'oreille, etc., 1878.
[4] Buck: Ann. Journ. of Otology, 1879.
[5] Ravogli: Congressber., Mailand, 1880.

mucous patches, is a strong argument in favor of the specific origin. The presence of ulcers in the adult auditory canal should excite suspicion that they have had their origin in syphilis; and on the subject of diagnosis in this connection Buck[1] calls attention to the fact that, while in children the external canal is apt to become ulcerated by the constant flow of an irritating discharge, it rarely occurs in adults, and when it does, usually only after an extremely chronic otorrhœa.

In considering the affection it should also be borne in mind that polypi are almost always larger and more discrete, and a pedicle can often be made out on careful examination.

The diagnosis in syphilis of the external canal is very favorable, and under proper treatment stenosis rarely results.

The treatment should be both local and constitutional; constitutionally, the treatment should consist of the use of mercurials and iodide of potassa.

Politzer recommends the removal of the condylomata by silver nitrate or concentrated chromic acid, and then by brushing with corrosive sublimate (0.1 to 30.0) solution, or the tincture of iodide. Knapp advises dusting with calomel, and later one per cent solution of silver nitrate.

IODOFORM DERMATITIS

By A. HERZFELD, M.D.,

NEW YORK.

ASSISTANT TO THE CHAIR OF PATHOLOGY AT THE NEW YORK POLYCLINIC.

The number of cases of iodoform poisoning resulting in constitutional symptoms is a very large one, as a review of medical literature shows; less numerous are the cases where this drug has caused in its local application affections of the skin of a more or less severe nature. All the dangers of iodoform medication have sufficiently been described, but the case in question has some points of interest which seem to make it worthy of publication, and again should call the attention of the medical profession to the dangers which can follow the use of iodoform, even in very small quantities. The case occurred in a young man, who contracted a gonorrhœa two years ago, of which he never was cured entirely. He had always had a "goutte militaire" and the shreds characteristic of a chronic affection of the urethra: a chronic anterior urethritis. He consulted a well-known physician in this city last March, who found, on examination with a bougie à boule, a stricture 3 ctm. behind the meatus. At that time a sound, No. 21 French, was passed, to dilate this constriction; on the withdrawal of the sound a considerable amount of bleeding occurred, caused by the "violent rupture of the constricting parts." About one week after the hemorrhage, a No. 25 French sound was passed without further difficulty, and causing only a slight amount of pain, but micturition was still painful at that time. To accelerate the process of healing of the wound made in the urethra, bougies of a 6.5 ctm. length were used, and of the following composition:

Iodoform	0.1
Butyrum cacao	0.3

The patient being an apothecary, the best obtainable iodoform was used and the bougies were carefully prepared. These bougies were introduced three times a day, for two days in succession, hence six in all were used, which equals 0.6 iodoform. On the morning of the third day after starting the use of the bougies, the patient called attention to a redness extending over the penis and scrotum. During the day this erythema increased rapidly, and extended toward evening, shading off into a macular eruption over the upper third of the thigh and regio pubica. A dermatitis was diagnosed and at once referred to the use of the iodoform. The skin and subcutaneous tissue over the penis and scrotum were in a state of acute inflammation. The patient remarked at that time, that he was unable to tell the scrotum from the penis. This swelling lasted three days, and on the fifth day the swelling of the parts subsided, except that of the lymphatic glands in the groin, which still were easily palpable; no constitutional symptoms appeared. To reduce the swelling of the parts, hot aqua plumbi was applied. The urine, which was examined at that time, five days after the onset, still showed gonorrhœal threads.

From the onset of the attack no further medication than aqua plumbi was used, nor any sounds passed. Ten days after the onset of this attack, and five days after its subsidence, the same erythema again developed over the same regions above mentioned, the same swelling of the parts set in. As no medication of any kind had been used, we were at a loss for its explanation. On questioning the patient, we found that he changed his underwear on the morning in question; this had not been properly washed, and pieces of the molten bougie were found still adhering to the fabric, and a strong odor of iodoform was still very apparent. Again the diagnosis of an iodoform dermatitis was made. At this time the patient developed a marked aversion to iodoform, the odor of which caused nausea and vomiting. A second attempt was made to reduce the swelling by hot aqua plumbi. On the second day the skin over the penis and scrotum ruptured in various places, and a thick, tenacious, colorless liquid exuded. The pains were distressing, and a ten per cent. solution of cocaine was applied continuously. The genitals, which were swollen about three times their normal size (testes, corpora cavernosa and spongiosum were not affected), were supported by a bandage. The exudation continued for three days, the distressing itching continuing during the new formation of the skin. But after five days the parts again took on a normal appearance. This second attack of an acute dermatitis can only be attributed to the iodoform, as no other medication was used at this time in any manner. If it had been a local sepsis caused by the absorption of discharges from the wound made in the urethra, why did it not set in sooner, but just exactly at the time when the patient changed his underwear, which still contained particles of iodoform, and the aversion to the odor of iodoform which causes nausea even at the present day, three and one-half months after subsidence of second attack? On examining the patient's urine at the present time, I still find a small number of gonorrhœal shreds, but his goutte militaire has entirely disappeared. I used lately an injection of argentum nitricum 1 to 2,000 into the anterior urethra.

Two weeks ago a furuncle developed on side of patient's neck, I opened it, and applied a moist carbolic dressing, two per cent., for two days. After this time I noticed a slight redness around the borders of the wound, and fearing a development of an eczema, I stopped the use of the carbolic acid at once, but I dusted a few grains of iodoform on the surface of wound. On my next visit I noticed a marked increase of the erythema, and the skin was in a state of acute inflammation. A typical eczema developed and continued seven days, characterized by profuse weeping, which was controlled after five days by the application of equal parts of starch and talcum. The furuncle healed under an aseptic dressing (without further treatment). The wound was washed with aqua destillata, and sterilized gauze was applied over it. This eczema I will not attribute to the use of the few grains of iodoform, as the erythema was developed undoubtedly by the use of the carbolic acid, but the iodoform may have aggravated it, as soon after its application the redness increased; the odor of the iodoform was not detected by the patient, as only a very small quantity was used and a dressing was applied over it.

In the first instance, where the bougies were introduced into the urethra, the absorption took place through the mucosa. Cutler reported two cases in 1886, where the absorption of the iodoform through the mucous membrane of the uterus in his first case, and through the mu-

[1] Buck: Manual of Diseases of the Ear, p. 100.

cous membrane of the vagina in his second, resulted both in a development of dangerous constitutional symptoms.

The second attack in our case must have been due to the absorption of the iodoform through the newly formed skin. The medium with which it was combined may have accelerated the development of its deleterious properties, as was shown in a case of Kreort,[1] where the drug caused a dermatitis only in combination with glycerine or oily substances; in the above-mentioned case of Cutler, where uterine bougies were used, each containing 0.3 iodoform (carcinoma of uterus); and similar case of Fuerst.[2] In our case butyrum cacao was used. Neisser reported two cases in 1884, where he observed the same symptom relating to the skin, and attributed it to a personal susceptibility to the drug. There is in our patient undoubtedly an idiosyncrasy to the iodoform, as up to this day he still has a marked aversion to its odor, which causes marked nausea. Fuerst reports another case (1886) where the use of the iodoform caused in the same patient an eczema every time, even "the mere odor was sufficient to do it."

At no time did our patient develop the slightest constitutional symptoms, and Taylor (1887) claims to have proven by statistics that in younger persons iodoform poisoning results mostly in affections of the skin, and in older people constitutional symptoms are developed.

Hence we see again that we have in iodoform not a harmless drug, that its odor is not its only objectionable quality, and the numerous cases of poisoning have called repeatedly the attention of the medical profession to the dangers which are connected with its use. Any attempt to find a good substitute, of which our materia medica contains a number devoid of such objectionable qualities, should be encouraged.

Clinical Department.

A BROKEN CATHETER IN THE URETHRA.

By WILL B. DAVIS, M.D.,

PUEBLO, COL.

Seeing the case of "A Broken Catheter in the Bladder," related by Dr. Ransom in your issue of June 24th, reminds me of an interesting case coming under my observation on September 15, 1892.

About ten o'clock on the morning of that day a gambler rushed into my office in a thorough state of alarm, holding all but about one inch of the eyelet end of a No. 12 F. gum catheter in his hand, which told its own tale. I satisfied myself by careful exploration that the broken end was still in the grasp of the deep urethra. He was a most unfavorable case for any kind of a cystotomy, and I was more than ordinarily anxious to relieve him without such an operation if possible; and inasmuch as he could urinate, notwithstanding the presence of the catheter in the urethra, I desisted from further interference at the time, but told him to go at once to his room, to remain perfectly quiet, and to eat all the water-melon he could hold, and when he felt his bladder well full of urine to come back to my office, only across the street from his room. He returned at 2 P.M., and said he could hold his water no longer. I had him empty his bladder with as much force as possible, hoping thereby to dislodge the catheter and drive it forward, but to no avail. I had him go back to his room, eat more melon, and return at five o'clock, with as full a bladder as possible. On his return I carefully passed a pair of Thompson's urethral forceps down to the broken face of the catheter, but owing to the general strictured condition of his urethra, I could not open them sufficiently to grasp anything. I therefore opened them as wide as they would bear, and withdrew them thus, hoping to dilate the urethra in front of the catheter. I then had him again expel the urine with force, when the piece of catheter came away readily, without pain or causing any subsequent inconvenience whatever.

PERSISTENT SINGULTUS—LAVAGE OF THE STOMACH.

By A. ERNEST GALLANT, M.D.,

ATTENDING PHYSICIAN, NORTHERN DISPENSARY, NEW YORK.

On June 1, 1893, F. B——, aged twenty three, single, German, night-baker, was referred to me at the above named dispensary, giving the following history: On May 29th he had pain and fulness in the head, with constipation. The next morning he had no appetite, and took only coffee for breakfast; he smoked three cigars during the morning, taking soup only at noon. At 5 P.M. he ate a piece of sour tongue, which was vomited about a half hour later. At 6 P.M. he ate a pickled green pepper, and soon after felt weak and dizzy. The body was covered with profuse perspiration, and he was annoyed by frequent paroxysms of hiccough. These attacks occurred through the night and for the two following days (except when asleep), and are now repeated every minute or two, being only relieved for a brief period by drinking soda-water.

The patient is of robust build, phlegmatic temperament, appetite and digestion usually good, and is feeling well in every respect except some pain in the epigastrium, and the annoyance caused by the hiccough.

The case impressed me as one of gastric origin, but having no stomach tube at hand I ordered cocaine hydrochlorate one-eighth grain, every three hours, and magnesii sulphas. half-ounce, once. This gave almost complete relief until June 3d, when the paroxysms began again. I then ordered pilocarpin hydrochlorate one-tenth grain, three times daily, as recommended by Stiller.[1] He did not hiccough during the day (June 4th), but suffered severely from it during the night. June 5th: Still hiccoughing and has vomited a greenish-yellow fluid, with much tenacious mucus, four times during the past twenty-four hours. The diet was limited to milk and vichy. June 6th: Did not work last night. Hiccough is almost as bad as ever. At 5 P.M. the stomach was washed out, requiring three quarts of warm water before the return fluid was clear and free from particles of undigested milk and very tenacious mucus. There has been no recurrence since.

In looking over the more recent literature on this subject, the best résumé of the treatment of which was given by Dr. F. W. Putnam,[2] I find no mention of lavage, though it seems to me especially fitting in cases where there are evidences of gastric irritation.

PROCEDENTIA UTERI COMPLICATED BY PREGNANCY.

By HILBERT B. TINGLEY, M.D.,

OCEANUS, L. I., N. Y.

Having seen a case of procedentia of the uterus in pregnancy, reported in Medical Record of 15th inst., I wish to report the following case as being particularly interesting:

On May 16, 1891, I was called to see Mrs. D—— K——, of Boston, at her home in Williams Street. I found her in labor, which had commenced some hours before. Upon examination I found a tumor as large as a cocoanut, with a dry, smooth exterior, which had the appearance of normal cuticle—which proved to be the uterus. Upon questioning the patient, she informed me that she had suffered from "falling of the womb" for years, and the appearances substantiated the fact.

Upon examination, I found the os dilated to the size of a silver dollar, and as the pains did not advance the labor, I passed my hand into the uterus and found the feet presenting, which I had no trouble in bringing down and completing the labor. After some little time respiration was established in the child, which was a perfectly formed boy.

The mother made a happy recovery, and was in good condition to be operated upon in due time.

IMPERFORATE HYMEN.

By H. D. THOMASON, M.D.,
ALBION, MICH.

The case of imperforate hymen reported by Dr. Charles E. Nammack in the issue of the Medical Record, July 15, 1893, recalls a similar case in my own practice which occurred some six years ago. The husband consulted me upon the delicate question of inability to secure satisfactory sexual relations with his wife, though married for more than a year. The situation was equally distressing to the wife, and serious domestic infelicities were threatened as a result.

The wife was a buxom-looking German girl, aged twenty-two, apparently the picture of health and strength. I learned from her, however, that she had never menstruated, but had regularly, every four weeks since fifteen years of age, suffered all the symptoms of normal menstruation except the appearance of fluid. Manual examination of the abdomen revealed a tumor the size of a gravid uterus at full term, and digital examination at the entrance to the vagina demonstrated a thick, integumented bulging — an imperforate hymen. Aspiration through this tissue was resorted to, but only a pint of thick, black, unoxygenated fluid was removed; its consistency was such that it refused to run readily through the largest aspiratory needle. The following day I made a free incision, under aseptic precautions, through the hymen, with the result of the sudden removal of a gallon of thick black fluid bearing a consistency and appearance of tar—the product of seven years' accumulation of retained menses. The patient made a rapid and complete recovery, and as I frequently see both husband and patient apparently well and happy, and hear no complaints from either, it is fair to presume the results of the operation have been satisfactory to all parties.

A CASE OF DYSMENORRHŒA.

By A. H. BROWNELL, M.D.,
ONEONTA, N. Y.

The following is the report of a case of dysmenorrhœa that may possibly be similar to the case reported by Dr. Bigelow in the Medical Record of July 22d.

Mrs. D——, a German woman, twenty-three years of age, married six years, no children, began to have pain at each menstrual period about two years after marriage. The pain gradually increased in severity. She was very regular, but the flow was scanty and lasted about two days. After each period the patient felt well and was free from inconvenience until a few days before the time for the next period, when pain would be felt several times a day, quite sharp, but lasting but a few moments at a time.

When I first saw her, eighteen months ago, she had worn many kinds of supporters, had taken a large variety of medicines, but without relief. Examination showed a uterus normal in size, slightly antiflexed. So far as could be detected, there was no enlargement of the ovaries, and but little tenderness. There was slight endometritis, with stenosis of the internal os, and extreme pain upon the passage of even the smallest probe, which the patient said was like the menstrual pain. Thinking I had found the cause of the trouble in the stenosis, I dilated fully, and for the two following periods there was entire relief from pain. Then the pain returned, worse than ever.

Dr. Vander Veer, of Albany, was consulted, and finding nothing wrong other than stenosis, advised dilating again and packing with iodoform gauze.

This was done, but the patient could not endure the gauze, having all the pain of menstruation so long as it remained. A vertebrated stem pessary was tried, but could not be worn.

In February last, Dr. Vander Veer made an exploratory incision and found both ovaries were cystic, but were only slightly enlarged. He also found that both tubes were doubled upon themselves in the form of a figure 8, and the loop was distended enough to admit the end of the finger into the tube.

The patient made an excellent recovery and has had no pain since, although the menstrual flow has twice recurred since the operation.

The following questions I have not been able to solve in regard to the case: Why did the dilatation give relief? Why, with such a condition, did permanganate of potash give relief for four months and then lose its power? (This under another physician.) How could a patient, who was not in the habit of taking morphine, take three and a half grains in six hours and not feel the slightest relief therefrom, when later for another condition ⅛ grain gave relief?

During the severe pain, complete anæsthesia under chloroform was the only means I could find of relief.

A DISCHARGE FROM THE MIDDLE EAR TEMPORARILY ARRESTED BY THE REMOVAL OF ADENOID GROWTHS FROM THE PHARYNX.

By ANDREW H. SMITH, M.D.,
NEW YORK.

Dr. Buck's article in the Record of July 29th recalls to my mind a case in which the counter-irritation resulting from the removal of adenoid growths from the vault of the pharynx was apparently the cause of a temporary arrest of a chronic discharge from the middle ear.

The patient, a lad twelve years of age, had suffered for two years from middle-ear disease, with a perforation through Shrapnell's membrane. The discharge was considerable in quantity and very fetid.

He was found to have large adenoid growths in the pharyngeal vault, which were removed with forceps and scraper. Following the operation there was a rapid decrease of the discharge, and for a short time even complete cessation. But with cicatrization of the denuded surface the discharge returned, and soon became as abundant as before.

It seemed probable that the extensive wound resulting from the operation had produced such active derivation from the middle ear as to suspend the suppurative action during its continuance.

TONGUE TRACTION IN ASPHYXIA NEONATORUM.

By CHAS. G. AMENDE, M.D.,
NEW YORK.

The fact that there has been considerable discussion in some European journals upon this subject will be my excuse for referring to the following modification of the original Esmarch treatment. The infant is placed upon its side or belly, and while the thumb of the left hand of the operator rests under the chin, the index finger upon the tongue at the root, the right hand is placed upon the chest. Then the chin and tongue are drawn forward in alternation with compression of the chest.

In a case last winter the first traction was followed by a sound like a smack, attributed to a loosening of the epiglottis, previously agglutinated, as it probably always is during intrauterine life. A full cry followed a few more tractions.

Progress of Medical Science.

The Influence of Diet in Chronic Bright's Disease.—At a late meeting of the Royal Medical and Chirurgical Society (*The Lancet*), Dr. Hale White read a communication on the Influence of Various Diets upon the Composition of the Urine and the General Condition of Patients suffering from Chronic Bright's Disease. He first referred to the opinions of many authors and pointed out that they were by no means unanimous as to the best diet for patients with chronic Bright's disease. He next showed that all the *a priori* reasons which had been urged in favor of milk or any other particular diet were fallacious, and that consequently the only way to attack the problem was to carefully observe the condition of the urine and the condition of the patient upon different diets. It was very necessary not to draw deductions from too few cases; he had therefore taken ten cases of chronic Bright's disease in which the urine had been carefully analyzed every day for many weeks, so that altogether between four and five hundred analyses of it were made. In each case notes were kept also of the general condition of the patient. The following diets were tried: Milk, three pints a day, containing 1,076 grains of proteid; farinaceous, consisting of bread and milk, containing 1,137 grains of proteid; full diet, consisting of bread, butter, milk, meat, rice pudding and containing 1,522 grains of proteid; and sometimes the effect of adding fish, eggs, or more meat was tried. The following results were reached: 1. Quantity of urine. Usually more urine was secreted upon farinaceous or milk diets than upon full diet. 2. Specific gravity. The diet had no certain influence on this, but on the whole it was lower on milk and farinaceous diets than on full diet. 3. The quantity of albumin passed. The figures showed that nearly always the albumin passed was more upon milk diet than upon farinaceous and less upon full diet than upon either milk or farinaceous diet. Even in the rare instances in which the maximum quantity was passed upon full diet the excess of proteid in the full diet more than compensated for any extra loss of albumin, so that patients always best avoided loss of albumin by a full diet. 4. The quantity of urea passed. The influence of diet upon this was most uncertain; often less urea was passed upon full diet than upon farinaceous and less upon farinaceous than upon milk. Sometimes the reverse was true. 5. General condition of the patient. The cases distinctly showed that full diet was not more liable to lead to uræmia than any other; in fact, in one patient full diet appeared to ward off uræmia and the patient ultimately recovered. The patients always felt and seemed much better and stronger on full diet, or on farinaceous diet with meat or eggs added, than on milk or farinaceous diet only. Many patients loathed milk diet and greatly disliked farinaceous diet; on the other hand, they relished full diet. Dr. Hale White therefore advised full diet, for it did not lead to uræmia nor was it harmful in any way, but it saved albumin, and the patients liked it and improved on it in all respects, while they greatly disliked other diets. If the diuretic effects of milk was desired, plenty of water should be drunk.

Lympho-sarcoma.—Professor Kundrat gavê a long paper on the origin, course, and result of these new plastic growths. Commencing as an enlargement of the lymphatic glands, they do not rupture the capsule, but distend them to great dimensions. They differ from other malignant growths by their influence on the surrounding muscles and fibrous tissue. Although different glands are affected in its progress they are not generally attacked, as in the case of pseudo-leucæmia or leucæmia itself. Though the surrounding tissue and muscles are implicated, they still remain separate from the mucous membrane, but never forming a stricture or shrinking as in polypi. In some cases small glands may become fused and assume one large growth, which seldom appears in polypous excrescences. From the primary lympho-sarcoma small nodules are transported to more internal organs, which do not convey the impression of common metastasis occurring in the lymphatic paths. These secondary formations take place in organs where metastasis seldom produces neoplasms, as the stomach and bowels. In very rare cases metastasis in the liver, spleen, kidneys, and bones is absent. The lympho-sarcoma may compress the blood-vessels, producing thrombosis, marasmus, or gangrene of the organ, but never in the vessel. Lympho-sarcoma appear in middle life, very rarely in children. He relates two cases which he has met before ten years of age, and two before fourteen, but the most are between twenty-six and sixty years of age. They appear usually in the strong and healthy, and affect the male twice as often as the female. In lympho-sarcoma very seldom healed tubercular glands are present, while in pseudo-leucæmia this is not uncommon. Pseudo-leucæmia and granuloma fungoides malignum are the two diseases which it most closely approaches. The former is distinguished from lympho-sarcoma by the absence of the spleen enlargement; on the other hand, it is more atrophied, and more resembling marasmus—the marrow of the bones paler, and here and there a gall-like color. The usual site of the lympho-sarcoma is the neck, mediastinum, retro-peritoneal and mesenteric glands, very seldom the inguinal glands, and more rarely the axillary glands. They occur frequently in the lymph follicles and mucous membrane. It is worthy of note that secondary tumors may be mistaken for primary ones. The most common are those in the neck, extending to the pharynx and producing stenosis. Those originating in the follicles of the pharynx, mouth, and tonsils, are the most interesting. Those on the tongue often ulcerate and cicatrize. Those in the mediastinal glands often produce hemorrhage. The primary lympho sarcoma of the stomach appears as a diffuse infiltration, in the bowel as a follicular enlargement or infiltrated swelling surrounding it, giving a spindle-form dilated appearance. The latter phenomenon distinguishes it sharply from carcinoma where stricture occurs.—*Medical Press.*

The Alleged Contagiousness of Leprosy.—From the report of the Leprosy Commission in India, published in part in *The Lancet*, April 29, 1893, we learn that at the outset of the chapter dealing with the vexed question of contagiousness it is pointed out that because a disease depends on a pathogenic germ it does not follow that it is contagious, and malaria and pneumonia are instanced as examples of infective non-contagious disease. Flügge's dictum that the diffusion of leprosy by contagion is exceedingly rare and can only take place under special and predisposing favorable conditions condenses much of the argument contained in the report. Surprise is expressed at Hansen's contagionist attitude in view of the fact, that he himself records, of the disease dying out among the Norwegian leper emigrants in America. The Commission emphasize the necessity of separating the "abstract and scientific meaning of the term 'contagion' from the practical one," and boldly declare that the actual question of contagion is not to be settled by bacteriological and laboratory experiment. They point out that great differences in point of contagiousness exist among the infective diseases, and they regret the tendency of modern research to disregard clinical and epidemiological experience in this matter. The transmission of tuberculosis is largely, if not wholly, governed by the disposition of the individual exposed to infection. From the evidence before them the Commission conclude that "though they consider leprosy an infective disease, caused by a specific bacillus, and moreover also a contagious disease, they are of opinion that there is not sufficient evidence that leprosy is maintained or diffused by contagion; indeed, under the ordinary human surroundings the amount of contagion which exists is so small that it may be disregarded, and no legislation is called for on the lines either of segregation or of interdiction of marriages with lepers." All the instances of alleged contagion brought under their notice broke down (with one possible exception);

in no single case could contagion or the possibility of contagion be actually demonstrated in a manner free from objection ; the assumed contagion in family leprosy could only be traced in five per cent. ; it is very rare for a wife to be infected by her husband, or *vice versâ* ; there is no evidence that vaccination diffuses the disease, and "the instances quoted in literature of leprosy being 'vaccinated' on to a healthy child are too equivocal and ambiguous to carry much weight." This and other evidence of the absence of communicability among those living and mingling with leper communities are adduced as arguments in support of the above important conclusion. Once more the comparison with tuberculosis is held to be the keystone to the interpretation of leprosy.

On the Treatment of Thread-worms in Children.—In the course of a clinical lecture on "Thread-worms in Children," published in the *Clinical Journal*, Dr. Sansom says: "As regards treatment in the case of the hosts of oxyurides, the indications are (1) to expel the intruders and all their ova ; (2) to prevent the entry of ova into the alimentary tract. The total expulsion of the parasites is no easy matter. It is important to keep up for several weeks a frequent aperient action ; castor-oil, sulphate of magnesia, rhubarb, or other simple aperients may be employed for this purpose. If the parasites present at the rectum, or if there be local symptoms hereabout, an enema is decidedly indicated, but the old notion that such clyster-treatment is the plan to be adopted in all cases, is quite erroneous. The habitat of the oxyuris is not the rectum only, but the whole large intestine, in fact, its headquarters may be said to be the cæcum. It is obvious that ordinary enemata cannot reach so far. In rebellious cases special apparatus, whereby the whole large intestine can be irrigated, are recommended. Such is Hegar's tunnel system apparatus. Nothing is better as a destructive agent than warm or cold (pure) water—in water the parasites swell up and burst. A solution of soap is sometimes recommended. After a general clearance by purgatives and enemata, it is well to instruct the parents to repeat the latter about once a week, even when the child seems in good health. With this purgative line of treatment it is, in my opinion, very important that a tonic plan should be joined. Indeed I think the facts show that a double cause exists for the accumulation of these intestinal worms, and for the effects which they produce. So long as the ova of the parasites are imported into, or even by chance develop in, a healthy intestine, they manifest no ill-effects, because the vigor of the intestinal movement never allows them to accumulate. Let there be, however, from any cause, a paresis of the bowel, or a development of the mucus in which they can become concealed, and then they become the dangerous pests that I have described. The moral is: Coincidently (or commencing very shortly after the first expulsive efforts) administer iron tonics with, in some cases, strychnine or nux vomica, with a view not only of restoring the blood-making function, but of giving strength to the weakened intestines. Finally, as regards preventive treatment, without which all other means are of no avail. At the outset insist on scrupulous attention to diet. All the milk given, and all the drinking water should be previously boiled, for ova of ascaris lumbricoides can be imported by these vehicles. So, also, all the meat given should be well cooked. Especially all the food should be clean. It is through the soiled fingers of human kind that the ova are chiefly distributed ; any article of food, therefore, which passes through many hands, or is liable to be touched by dirty hands, suspect. I am very much inclined to think that brown sugar is a vehicle for importation—therefore I order white sugar to my patients. Above all, try to indoctrinate habits of strict cleanliness as regards the little patients themselves. With the view of killing the ova I order tar or carbolic-acid soap to be used for the frequent washing of the body, and I make the parents keep the children's nails short, and brush them many times a day with tar-soap water. It is undoubted that the supply of the parasite is kept up by the conveyance, by the fingers, of ova from rectum to mouth. Alas, it is not always that these lessons can be adequately enforced, though I must say that among the poor I have found rebellion against carefully expressed rules exceptional. The mothers of hospital patients are willing, for the most part, to learn and glad to be taught. You may think my precautions unnecessarily minute ; but I hold that the treatment of the affections to which I have directed your attention is on a par with the antiseptic method in surgery."

Intermittent Hydronephrosis.—Dr. Marchant has observed two cases of intermittent hydronephrosis treated differently, but successfully. The first patient that he attended suffered for some years from pain in the right flank, and on examination the presence of a bilateral salpingo-ovaritis was discovered, as well as a nephroptosis on the right side (*Medical Press*). Laparotomy was performed, and the ligaments removed. The woman made a rapid recovery. However, a short time afterward great pain was felt in the right flank, accompanied with fever and vomiting, and at the same time it was discovered that the quantity of urine had diminished by one-half, and contained some pus. The kidney was very painful to the touch, and it was remarked that it had increased considerably in volume, and was surrounded by hard swelling ; the kidney was, besides, absolutely fixed to the wall. At the end of three days the painful symptoms disappeared, the urine regained its normal quantity and ceased to be purulent, and the renal organ recovered its mobility. A few days subsequently another attack took place, so that the patient solicited surgical intervention. M. Marchant, not willing to operate a second time on a patient already weakened by laparotomy, applied Glenard's belt for floating kidney. However, for several months subsequently the patient did not cease to suffer in spite of the treatment, and finally implored an operation. Nephrectomy was performed and a calculus of the pelvis sought for, but not being found, the kidney was fixed by suture to the surrounding tissue, and the wound closed. The patient made a good recovery and never suffered afterward. The second case was that of a young girl, aged twenty, anæmic, and consumptive looking, who presented in the left side a large fluctuating and painful tumor ; the quantity of urine had greatly diminished and contained pus. Suspecting the existence of hydronephrosis with purulent infection of the cyst, nephrectomy was performed and a drain placed in the wound. The following day the patient, who emitted two quarts of urine habitually, passed less than a pint. However, by degrees the quantity attained the normal standard. Histological examination revealed the tuberculous nature of the lesions. M. Tuffier thought that the mechanism of intermittent hydronephrosis was not fully understood, but he found in two cases the ureter twisted, so that the urine could not pass. As to the choice of operation, he preferred nephropexia to nephrectomy when the kidney was not too much damaged.

Diffuse Popliteal Aneurism Caused by an Exostosis.—Terrier and Hartmann record an interesting case of diffuse popliteal aneurism. The patient was a youth of seventeen years of age, who, while dressing after a bath, was seized with severe pain in, and radiating from, the right ham, and coldness of the foot. Soon afterward a pulsating swelling low down on the inner side of the thigh was noticed. About a month after the onset of the trouble he was admitted into the Bichat Hospital and then presented a very great swelling, occupying the lower half of the thigh, the knee, and the upper part of the leg ; the pulsation in it was only slightly marked. It was diagnosed as a diffuse aneurism, and M. Terrier determined to try to save the patient's limb. Having placed an Esmarch bandage around the thigh he made a very free incision over the ham, turned out a large quantity of clot, and then found a longitudinal aperture in the popliteal artery exactly opposite, and evidently caused by, a

pointed exostosis growing from the inner supra-condyloid ridge. The injured portion of the artery was cut out, the ends of the vessel ligatured, and the wound sutured above and below a large drainage-tube. The patient made an excellent recovery and left the hospital with the full use of his limb. In this case the exostosis sprang from the bone well above the epiphyseal cartilage and was evidently an exaggeration of the irregularities met with in the supra-condyloid ridge of the femur; other less marked and less pointed projections studded the ridge. Before the operation the patient was febrile, but blood taken from the aneurism and cultivated was found to be sterile; the fever was not due to organisms, but to some products of the extravasated blood. Many years ago a similar case was recorded by Dr. Boling in the *North American Medical Chirurgical Review*. Amputation of the thigh was performed and the man recovered. Such an accident must be exceedingly rare, as, although exostoses of the lower end of the femur are quite common, they are usually too rounded and smooth to pierce an artery. In Dr. Boling's case the exostosis was a true epiphyseal outgrowth; in M. Terrier's case it was due to ossification of the tendinous insertion of the abductor magnus muscle—quite distinct morphological conditions. —*The Lancet.*

Too Much Importance Attached to the Tonsils.—In the experience of Dr. Farlow (*Boston Medical and Surgical Journal*) treatment of the nose and post-nasal space is productive of more good to the pharynx and tonsils than treatment of the tonsils is to the nose and post-nasal space. He believes that the days of wholesale slaughter of large tonsils, without regard to structures higher up, will some day have an end. He presents the following conclusions: 1. Because the tonsils are easier to see than the nose and post-nasal space is no sign that they are more important than the latter. 2. Form no estimate of the size of the tonsils unless you see them in repose. 3. Always examine the back teeth and the base of the tongue. 4. In acute follicular disease of the tonsils, look for and treat disease of the other follicular tissue in the throat. 5. Nasal obstruction, cough, and impaired voice are much more likely to be due to nasal or post-nasal hypertrophy than to tonsillar. 6. The fact that the tonsils are enlarged or diseased should lead us to look for a possible explanation in the parts higher up. 7. Free the nose and the post-nasal space in addition to, or instead of, tonsillotomy, if you wish to improve the voice and respiration.

Eclampsia in Children Induced by Hernia of the Cæcum in the Inguinal Canal.—Dr. Feurer has reported two cases of non-incarcerated hernia of the cæcum in the inguinal canal in children, attended with convulsions, and in one case terminating fatally. The first case was that of a child, six months old, in which a right-sided inguinal hernia had been observed from the sixth week. A truss had been worn, but failed of its purpose. The hernia would occasionally escape and be irreducible for days, and then finally return spontaneously. There had never been symptoms of incarceration. On one occasion the hernia could not be reduced, and symptoms of obstruction appeared, together with convulsions. Herniotomy was decided upon, but during the inhalation of chloroform the hernia was reduced by taxis. A short time later the child was again seized with convulsions, which, it was noticed, usually occurred before the bowels were moved and gas was passed, and in one paroxysm death took place, in the absence of symptoms of obstruction. Upon post-mortem examination the vermiform appendix was found in its entire length in the inguinal canal, with its extremity adherent to the testicle. There was no evidence of inflammation or of constriction of the bowel. The second case occurred in a child, five months old, likewise with an inguinal hernia that had been observed from the sixth week. For some time convulsions had occurred at the time of stool. Although the hernia was readily reducible, the experience of the previous case led to the performance of a radical operation. In the hernial sac were found the appendix, which had formed numerous adhesions, and the cæcum. The child recovered, and the convulsive seizures did not again occur.—*The Medical News.*

Jaundice in Syphilis.—At the recent German Medical Congress, Senator spoke on jaundice and acute yellow atrophy of the liver in syphilis. He said that jaundice in syphilis had been frequently described. It is to be distinguished from the usual catarrhal jaundice only by the fact that it disappears on specific treatment. From the benign course which it generally takes the morbid anatomy has not been studied. Gubler thinks that it arises from an affection of the mucous membrane of the gall-bladder. As rashes appear on the skin in syphilis, so similarly might exanthematous eruptions form on the mucous membranes of the biliary passages and lead to mechanical blocking. Others are of the opinion that lymph-glands, which enlarge as a result of syphilis, produce the jaundice mechanically by pressure on the bile-ducts. Reimers was the first to call attention to the occurrence of acute yellow atrophy of the liver in syphilitic subjects. He had observed three cases, a fact which suggests at all events some connection, in the face of the rarity of the affection. Senator had seen two cases in recent syphilis, one of which recovered. Both were in women. The cases that have been recorded in medical literature number about nine or ten, of which seven have been females. Perhaps the acute yellow atrophy is only an extension of the same process which produces jaundice. —*Berliner klinische Wochenschrift.*

Thiuret.—It is said that thiuret, with the formula $C_2H_7N_5S_2$, possesses the property of readily yielding its sulphur molecules in a nascent condition. On this depends its value as an antiseptic. It is a crystalline powder, almost insoluble in water, sparingly soluble in alcohol and in ether, and having feeble basic properties. Treated by alkalies, thiuret gives up sulphur and forms the ammoniate of phenyldithiabiuret and aniline. Heated to 105° C. in a closed tube, the salt decomposes, yielding sulphur, carbonic dioxide, ammonia, sulphuretted hydrogen, and the amyde of methylene, amidophenylmercaptan of Hoffman. Dr. F. Blum, of Frankfort, describes it as an active bactericide. He employed the hydriodide, chlorhydride, ortho-crespinate, borate, and para-sulphophenate; the last he considers the most suitable for therapeusis; it is a yellow, crystalline powder, with a faint odor, but of an intensely bitter taste, soluble in water in the proportion of three to four parts in a thousand; insoluble in alcohol, ether, and oil. Administered internally it provokes purging.

Phenosalyl.—Dr. Blanc summarizes the literature of this drug, which about six months ago was presented to the profession. It is a sirupy liquid, colorless, having an aromatic odor, very soluble in alcohol and glycerine, and in water to the extent of seven per cent. As it changes color to a brown on exposure to the light, it should be kept in blue bottles. It is made by mixing phenic, lactic, and salicylic acids in definite proportions (which are not given) at a temperature of 284° F., and after fusion adding menthol and eucalyptol, and on cooling the product is dissolved in twenty-five per cent. of glycerine. For the sterilization of instruments a two per cent. solution, five to ten minutes of contact, is sufficient. Sterilization of garments soiled by pure cultures of cholera bacillus, by immersion in a ten per cent. solution, is complete in one minute. Tuberculous expectoration is sterilized in from five to fifteen minutes by a two per cent. solution, so also are urines and putrefied blood. On the other hand, in experimental work, its administration has not resulted in the death of the animal, hence it may be considered to be of feeble toxicity. It has been employed in vaginal douches, one per cent.; in endometritis, twenty-five per cent. in glycerine; as a caustic in vaginitis, radical cure in six to eight days has followed the use of tampons wet with a two per cent. glycerine solu-

tion. In conclusion, this product appears to be more antiseptic than phenic acid, but a little less so than sublimate. On the other hand, it is infinitely less poisonous than the latter.—*Revue de Thérapeutique Médico-chirurgicale*, 1893, No. 6, p. 156.

The formula as given in the *Bulletin of Pharmacy*, 1893, No. 3, p. 118, is: Lactic acid, 31; salicylic acid, 15; menthol, 1½; carbolic acid, 140 parts. The three acids are melted, and the menthol added.—*American Journal of the Medical Sciences.*

The Lochia.—At a recent meeting of the Obstetrical Society of London, Dr. Giles read a paper on the "Lochia," giving the results of investigations on the quantity of them after labor. The conclusions derived from observations on sixty cases are as follows: 1. The average normal quantity of lochia is about 10½ oz. 2. The duration of the discharge is on the average nine or ten days. 3. The degree of parity does not influence the quantity. 4. Non-suckling does not increase the discharge. 5. The quantity is generally greater in women up to the age of twenty-five. 6. The weight of the child has a slight, and that of the placenta a well-marked influence, the quantity increasing with the weight of the placenta. 7. The quantity increases with the amount of hemorrhage at the time of labor. 8. The lochia are more abundant in the case of those who habitually menstruate profusely. 9. The quantity is generally great in the case of women of dark complexion. The difference between Gassner's results—viz., 52¼ oz —and his own—viz., 10½ oz.—is attributed mainly to the use of antiseptics and partly to the effect of astringent douching. The factors that influence the quantity of lochia were discussed. Dr. Giles believed that the three discharges—during menstruation, during labor, and during the puerperium—varied simultaneously, the quantity depending on predisposing conditions, of which the amount of pigmentation was generally an index, and that all three discharges were habitually more profuse in dark women.

Iodoform and Nitrate of Silver in Lupus.—It is stated in *The Lancet* that a Russian physician, Dr. Shlapoverski, has found the caustic action of nitrate of silver in contact with iodoform very efficacious in the treatment of lupus. In an obstinate case he scraped away all the large nodules and applied nitrate of silver, afterward covering the parts with collodion containing ten per cent. of iodoform. The treatment was renewed daily. In three months there was a decided improvement, and in seven months the parts were entirely healed. There has been no re-occurrence though more than four years have elapsed since the treatment was discontinued.

Preserving Vaccine Lymph in Hot Damp Weather.—Dr. Pedley, of Rangoon, writes to *The Lancet* that in the moist hot climate of India the great obstacle to the preservation of animal vaccine paste has hitherto been the difficulty of storing it so as to prevent its contact with the "living air." The air, at all times and especially during the rainy season, is laden with vegetable germs; one's boots acquire over night a bloom of mildew; paste or glue of any kind soluble in water becomes food for bacteria and moulds, so that book-bindings and instrument-cases, if not otherwise securely fastened, fall to pieces, and even glycerine, if exposed for a few days, affords nourishment to a luxuriant growth of black mould. The paste is prepared by thoroughly mixing the scrapings of the vesicles with glycerine, but the difficulty has been to preserve it when so prepared. The writer has tried various kinds of receptacles, such as small porcelain jars with screw lids, homœopathic vials with cork stoppers, etc., but with disappointing results. He finally hit upon the idea of using tiny collapsible pewter tubes with screw caps, and finds that they answer the purpose admirably. After the scarification has been made the screw cap is removed and immediately replaced as soon as a particle of the paste has been squeezed out of the tube. In this way it is exposed to the air for a few seconds only, and the opened end of the tube is so small that the danger of any germs lighting upon the contained paste is very slight.

The Height of Man.—A French statistician has been studying the average heights of men at different periods of the world's history and has reached some alarming conclusions. The recorded facts extend over nearly three centuries. It is found that in 1610 the average height of men in Europe was nearly 5 feet 6 inches. In 1790 it was 5 feet 6 inches. In 1820 it was 5 feet 5 inches and a fraction. At the present time it is 5 feet 3¾ inches. It is easy to deduce from these figures a rate of regular and gradual decline in human stature, and they apply this, working backward and forward, to the past and to the future. By this calculation it is determined that the stature of the first men attained the surprising average of 16 feet 9 inches. The race had already deteriorated in the days of Og, and Goliath was quite a degenerate offspring of the giants. Coming down to later time, we find that at the beginning of our era the average height of man was 9 feet, and in the time of Charlemagne it was 8 feet 8 inches. But the most astonishing result of this man's study comes from the application of the same law of diminution. It is conclusively shown that in 4000 A.D., the height of the average man will be but 15 inches, and in a few thousand years more the end of the world will come, for men will get so short that there will be nothing left of them.—*Buffalo Express.*

Treatment of Sprained Ankle.—Dr. V. P. Gibney advocates (*The New York Polyclinic*) the treatment of sprained ankles by the use of strips of adhesive plaster. Dr. Gibney owns his indebtedness for the new method to a little book by Mr. Edward Cotterell, of the University College Hospital, London. It was not until the end of 1888 that the treatment advocated in the brochure was fully digested and put into use by Dr. Gibney. He had all through his previous surgical career looked upon a sprain as a kind of mystery "not always so bad as a fracture, but sometimes more tedious," requiring fomentations for a little while, then a fixed dressing of plaster of Paris or silicate of sodium, crutches perhaps, and rest and massage afterward. He had never been attracted toward these methods, and he had come to expect a "stiffish" joint in nearly every case that came under his charge. His first case to be tried according to Cotterell's plan was that of a lady who had wrenched her right ankle severely. The usual external features of a sprain were present; no dislocation or fracture could be made out. Dr. Gibney first cut strips of rubber adhesive plaster about half an inch in width and long enough to completely encircle the foot. Then, with the foot well raised, he strapped it, the ankle, and the lower third of the leg with these strips, very much as if he had had an ulcer to treat. The first strip was carried over the outer side of the foot from near the base of the little toe. The second strip crossed the first, the third lapped over the first, the fourth overlapped the second, and so on, until at the conclusion he had practically constructed a Scultetus's bandage of adhesive strips extending far enough to include the lower third of the limb. Over this he placed a cheese-cloth bandage to help the plaster strips to adhere to one another and to make the dressing more tidy. The patient was told to put on her stocking and shoe and to walk about the room. The walking was accomplished with some diffidence, but with no real difficulty. She was made to walk the next day and went out shopping without any bad results. The recovery was without relapse, and the usefulness of the ankle-joint was unimpaired.

A Simple-Minded Man writes to an English contemporary to inquire whether it is proper for members of a medical society to consult with herbalists.

Yeast Destroys the Typhoid Bacillus, or at least takes away its power for evil, so says Dr. Springthorpe, by means of an acid which it secretes.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, August 19, 1893.

THE PUNISHMENT FOR THE CRIME OF PRODUCING ABORTION.

THIS crime has been particularly rampant in this city in the past year. A statement of the punishment accorded to it in various countries of Europe may therefore prove interesting. In England and Ireland the punishment is penal servitude for life, or a less term. Should the mother die, the crime becomes murder, which may be punished by death. In Scotland (says *The Lancet*) the punishment is arbitrary; in France, Spain, the German Empire, Austria, Hungary, Italy, Russia, Norway, Sweden, and Denmark—in short, throughout the whole of Europe—the crime is punished with imprisonment for from six months to twenty years, or for life. In Sweden the penalty is death if the mother dies; and in Russia the mother, if a consenting party, may be exiled to Siberia; in the Dominion of Canada the penalty is imprisonment for life: in Nova Scotia, Quebec, Ontario, British Columbia, and in Prince Edward Island it varies from imprisonment for two years to for life; in New Brunswick the penalty is death; in Australia and New Zealand the punishment is very severe, ranging from two years' imprisonment to penal servitude for life; in the United States it is punished with fines ranging from $100 to $5,000, with imprisonment for long periods, and with death.

There is, as will be seen, a very general unanimity of view regarding the high degree of criminality of the practice. Despite all this, the crime is increasing both in our country and in Europe. There is no doubt that this is due to the fact that many more women than formerly know of the possibility of abortion and refuse to accept the consequence of indiscretion or the responsibilities of maternity. There is but one way to look at it, however—abortion involves the destruction of one life and danger to another. Hence it is a crime never to be justified even under extreme circumstances.

It is true that many obstetricians still regard the induction of premature labor, even before the infant is viable, as a necessary measure in certain very rare cases. But the indications for it are becoming more and more restricted as medical science advances, and it is not improbable that the time is near at hand when the operation will no longer be thought of as a means of saving life. This legitimate obstetrical procedure, however, has nothing in common with criminal abortion, and medical men owe it to the community as well as to their profession to assist in limiting the work of those whose trade is infanticide. The daily papers could, doubtless, do more than any other agency toward abolishing the crime if they would consent to give up the small fees they get for advertising this class.

THE LOW DEATH-RATE OF THE TENEMENT DISTRICTS.

WE have several times called attention to the remarkable fact that the death-rate in the crowded portions of this city was really less relatively than in the more wealthy districts. This curious phenomenon has been rediscovered by Mr. Marcus T. Reynolds, who comments upon it in his prize essay on "The Housing of the Poor."

Mr. Reynolds points out the evils of crowded tenements, moral and physical; but he then shows that the death-rate of the tenement-house population of New York is slightly lower than that of the remaining population of the city, or, in other words, is highest in the houses containing the fewest inhabitants. It seems that the death-rate of persons of five years of age and over decreases with the increase in the number of tenants, while the death-rate of children under five years increases until there are more than eighty tenants to a house, after which it decreases. The explanation of Mr. Reynolds is that the tenants of the larger houses are under closer sanitary inspection, and also that the removal thence of the sick to hospitals is more frequent. He suggests, too, as a possible reason for the lower death-rate of the poorer classes that they pass much of their lives out of doors.

The hospitals are probably the most important factor in causing an apparently low death-rate in the tenement-houses. Thus in this city, to the 29,000 deaths in tenement-houses yearly, should be added most of the 9,800 deaths in institutions.

PROGRESS OF THE CHOLERA.

RUSSIA has again become the centre of interest in regard to cholera, as it was in the early part of last summer. Official returns show a great and sudden recrudescence of the disease during the past week, the number of cases reported for the week, from twelve provinces of the Empire, being 1,945, and of deaths 720. Nijni Novgorod is one of the most afflicted places. In the week ending August 13th, the fresh cases there numbered 260 and the deaths 105. In Moscow there were 47 new cases and 16 deaths on Sunday last. The increase in the number of cases is attributed in part to the intense heat which is prevailing throughout South Russia. Strict precautions have been taken on the eastern frontier by the Prussian authorities. The whole frontier has been closed except at two places, where all arrivals are examined and suspicious cases are subjected to a seven days' quarantine. A despatch from Berlin, dated August 15th, brings the news of three more deaths from cholera in that city. The disease still prevails at Sulina and Brahilov in Roumania.

Dr. Young has cabled to Surgeon-General Wyman that, as near as he can ascertain, the condition in Naples is improving. Official statistics show that during the week ending August 10th, there were 258 cases of cholera and 121 deaths from the disease in Naples. On the island of Capri, twenty miles from Naples, there were

during the same period 14 cases and 8 deaths. The disease is spreading to other coast towns, and an outbreak is reported in Campobasso, a town to the north of Naples on the other side of the Apennines. The Government has ordered that a physician and a sanitary corps accompany every train running between Naples and Rome. Signor Carloni, Director of Posts and Telegraphs, who was sent to Naples a few days ago on business, was attacked with cholera a few hours after his arrival and died on the following day.

Considerable alarm is felt in Vienna, and an official statement issued by the Sanitary Council of Austria declares that the condition of the country with regard to cholera is precarious—much more serious than it was in 1892. The Home Office sent a circular to the government officials throughout the country enjoining the strictest precautions. Cholera has broken out among navvies—mostly Italians and Croatians—building a railway at Marmaros, on the Galician frontier. Thirty-five died before the nature of the disease was recognized, and a panic seized the survivors, who fled in the direction of their homes, without even waiting for their wages. Seven cases of cholera and two deaths have occurred at Czerna-Gora, in the Carpathian Mountains in Galicia.

The Marine Hospital surgeon stationed at Antwerp has notified the Washington authorities that several cases of the disease have occurred in that city. Two deaths from cholera are reported to have taken place at Grimsby, on the North Sea coast of England.

Eighteen of the passengers on the Karamania, which arrived here from Naples on August 3d, and was detained at quarantine, have been attacked by cholera, and one has died. The passengers are still detained, but the ship, after a thorough disinfection, has been released and allowed to proceed to her dock in Brooklyn and to discharge her cargo.

A BUREAU OF PUBLIC HEALTH.

In the present number we publish the completed text of the Bill prepared by the Sub-Committee of the Quarantine Committee of the Academy of Medicine. The Bill in its present form may be said to be still a first draft, for it is the purpose of the Committee to revise it in accordance with such suggestions as may be made which shall appear to be important. The Committee seem to have very carefully reviewed all the measures which have heretofore been submitted to Congress, and to have embodied in their Bill whatever was necessary to render it complete in all of its details. We trust that all who are interested in this subject will aid the Committee with suggestions, and thus enable the Academy to perfect a measure which will receive the endorsement and support of the entire profession.

ELECTRO-THERAPEUTICS.

An interesting phase of modern therapeutics is the passing of electro-therapeutics from the hands of neurologists to those of surgeons and gynecologists. It is within the memory of some when electro-therapeutics meant neurology. The first special society for nervous diseases in this city was, if we remember correctly, a Society of Electrology and Neurology. Now the President of the American Electro-therapeutical Society is a gynecologist. We have on our exchange list three electro-therapeutical journals, all of them edited by gynecologists or gentlemen engaged more or less in this department. This change is not due to the fact that neurologists use electricity less, but that surgeons use it more. The change has been attended with some good results. There has been an improvement in electrical instruments, and particularly in our knowledge of how to use, measure, and control powerful currents. Opinions seem to differ as to whether gynecological therapeutics has been helped by the addition of electricity, but no doubt the exact status of this powerful agent will before long be determined.

RECIPROCAL RELATIONS BETWEEN THE MEDICAL BOARD AND THE BOARD OF MANAGERS IN HOSPITALS.

We have not infrequently had occasion to advert to the matter of the recognition, or to the lack of recognition, of the medical staff of a hospital by its Board of Managers. At times the latter see fit to drop—practically to expel—a faithful physician or surgeon, absolutely without cause other than that some other man wants the place; while at other times the relations between the two boards are, to say the least, most seriously strained.

It is pleasant to know that there are hospitals in which the relations are harmonious and mutually helpful, and it is with much pleasure that we call the attention of the readers of the Record to the following extract from the address made by George Macculloch Miller, Esq., President of St. Luke's Hospital, in this city, on the occasion of the laying of the corner stone of the new hospital. In the course of his remarks Mr. Miller said:

"Whatever the discoveries and progress of medicine and surgery have yet in store, whatever the benefits to result from these, let us not fail to recognize what has been accomplished through their judicious adoption and intelligent application by the physicians and surgeons, our medical and surgical staff, who, throughout its existence, with constant zeal and indiscriminating skill, have given their time and their talents to the patients in St. Luke's.

"I do not think sufficient recognition has been made of what the medical men of New York have always done, and every day in every week continue to do, for the sick poor in our hospitals; and I rejoice in this opportunity for making such recognition, as well as for presenting to the Medical Board of St. Luke's my acknowledgment that to them are due in largest measure both the credit and the thanks for the distinguished position she holds to-day among the hospitals of the country."

THE MILLENNIAL OF CREMATION.

The success of a particular form of mortuary disposal is a curious thing to celebrate. The cremationist, however, has always been something of a sentimentalist, and he has naturally felt warmly, even superheatedly, regarding his pet process. A cremation company in this city recently celebrated its one thousandth combustion. We do not know the exact nature of the celebration, except that there were speeches and flowers: the customary addition of champagne and a cold collation was probably admitted.

The company has just finished a new Columbarium. The statistics of its work are interesting. Up to the present time 1,010 persons have been cremated, classified as follows: 650 men, 270 women, 53 boys, and 35 girls. Of the total number, only 335 were native Americans. The others were of many nationalities. Germany led with 510, England was next with 34, and other countries were represented by one or a few.

There is no doubt that the agitation over cremation has done some good by calling attention to the possible dangers of cemeteries.

The actual danger of the cemetery and of earth burial, however, has never been demonstrated. It will be quite possible to bury a person safely for many years to come.

News of the Week.

American Electro-Therapeutic Association.—The following is the preliminary programme of the American Electro-Therapeutic Association, which will hold its third annual meeting in Chicago, September 12th, 13th, and 14th:

Discussions.—"What are the Possibilities of Electricity in the Treatment of Fibroid Growths?" Discussion will be opened by Dr. J. H. Kellogg, of Battle Creek, Mich. "The Influence of Frequency of Interruptions and Character of Induced Current Waves upon Physiological Effect." Discussion will be opened by Professor J. W. Morton, of New York.

Papers.—"The Nutritional Effects of Statical Electricity," by Professor W. J. Morton, M.D., of New York; "Electro-medical Eccentricities," by Newman Lawrence, M.I.E.E., of London, England; "The Graphic Study of Electrical Currents in Relation to Therapeutics," by J. H. Kellogg, M.D., of Battle Creek, Mich.; "The Action of the Continuous Current within the living Tissues, as distinguished from the Local Polar Action," by Professor W. J. Herdman, M.D., of Ann Arbor, Mich.; "The Therapeutic Application and the Theory of Alternating Currents," by Dr. Georges Gautier, of Paris, France; "The Treatment of Fibroid Tumors with Electricity," by Dr. Georges Gautier, of Paris, France; "Induction Coils," by Mr. A. E. Kennelly, of the Edison Laboratory; "Electrolysis in Tumors of the Bladder," by Robert Newman, M.D., of New York; "The Present Position of Electricity in the Treatment of Ectopic Gestation," by A. Brothers, M.D., of New York; "Electro-Therapeusis in Salpingitis," by W. B. Sprague, M.D., of Detroit, Mich.; "Report of a Case of Ascites cured by Galvanism," by Holford Walker, M.D., of Toronto, Canada; "The Primary Action of the Galvanic Current on the Blood. It increases the Amount of Ozone it contains, as shown by Chemical Tests of the Blood in the Arteries," by J. Mount Bleyer, M.D., and M. M. Weil, M.D., of New York; "The Conservation of Energy as a Successful Factor in Electrotherapy," by Horatio R. Bigelow, M.D., of Philadelphia; "Synovitis treated by Cataphoresis," by F. H. Wallace, M.D., of Boston, Mass.; "The Use of Static Electricity in the Treatment of Incipient Insanity," by W. F. Robinson, M.D., of Albany, N. Y.; "Further Study of Electrical Anæsthesia and Frequency of Induction Vibration," by W. F. Hutchinson, M.D., of Providence, R. I.; "The Absorption of Fibroid Tumors by Mild Electric Currents," by R. J. Nunn, M.D., of Savannah, Ga.; "Some Observations on the Fine Wire Coil or Current or Tension," by H. E. Hayd, M.D., of Buffalo, N. Y.; "The Treatment of Subinvolution by Electricity," by C. G. Cannaday, M.D., of Roanoke, Va.; "Successful Treatment by Electrolysis of four Additional Cases of Œsophageal Stricture, with Exhibition of Two Cases," by D. S. Campbell, M.D., of Detroit, Mich.; "The Treatment of Dysmenorrhœa by the Galvanic Current," by A. Lapthorn Smith, M.D., of Montreal, Canada; "Notes upon some Uses of Galvanism in Surgery," by W. B. D. Beaver, M.D., of Reading, Pa. Several other papers of equal interest have been promised, but the titles have not yet been received. MARGARET A. CLEAVES, *Secretary*

Yellow Fever.—The State Health Officer of Florida has been investigating the two cases in Pensacola which were reported as yellow fever by the Escambia County authorities, and announces that there was nothing in the clinical history or post-mortem findings of one of the cases to justify the diagnosis of yellow fever, and that the other was at the most only suspicious. No new cases have appeared in Pensacola, and every possible precaution has been taken by the army and navy authorities to protect their respective detachments at that point. Dr. Branham, of the Marine Hospital Service, who had just been ordered to Brunswick, Ga., to take charge of the quarantine station at that point, was taken ill soon after his arrival with symptoms suggesting yellow fever. Charleston has ordered a quarantine against Brunswick and other cities in which suspicious cases have occurred, as a precautionary measure. One hundred and twenty-six deaths from the disease were reported in Havana during July.

A Possible Cause for Appendicitis.—Dr. C. F. Crehore offers, in the Boston *Medical and Surgical Journal*, a suggestion accounting for the present prevalence of appendicitis. Looking beyond food and clothing as etiological factors, he finds in one particular a condition of recent origin which may possibly explain in some degree the frequency of the disease. This is "the comparatively recent and very general introduction of methods of physical culture and the resultant growth of athletic sports. Calisthenics, as generally taught, appear harmless enough; but many of the postures involved cause a good deal of abdominal pressure. It goes without saying that where an overloaded ascending colon is subjected to such pressure, a portion of the fluid matter entering from the ileum might be forced downward into the appendix and be the cause of serious disturbance. The danger from such a contingency would naturally be increased in the more violent gymnastics and the rougher atheletic games—as base-ball or foot-ball, rowing, polo, and the like. The position of the modern bicyclist when riding seems very favorable to an injury of that description."

Hypnotism in Russia.—An official notice has been issued in Russia that "physicians shall have the right to make use of hypnotism in the treatment of their patients. In every case of the application they must inform the administrative authorities, at the same time giving the names of the physicians in whose presence the patient was hypnotized."

Dr. R. F. Dill, for several years Professor of Midwifery in Queen's College and coroner for Belfast, died in that city at an advanced age on July 17th.

Centenarians.—The deaths of three persons, each over one hundred years old, were recently announced in an issue of the Philadelphia *Press*. One died in Collinsville, Mass., at the age of one hundred and seven years, a second in Taunton, Mass., aged nearly one hundred and one, and the third in Springfield, O., aged one hundred and three years. All were women, and all married, one being survived by her husband.

Dr. Mathias Wolf, of Brooklyn, died a short time ago from an overdose of morphine, taken, it was supposed, with suicidal intent.

To be Buried Alive.—A "mind reader" in Illinois has published his intention to be buried alive and remain in the ground while a cup of barley is being grown over his grave. He has read of the Man with the Broken Ear, and thinks he can give him points on his peculiar specialty.

Queen Victoria was recently reported to have had a stroke of apoplexy, but the news was contradicted the next day and the assurance was given out that her Majesty was in fine health and enjoying life in a quiet way in the Isle of Wight.

Dr. J. B. Burneson, of Luzerne, N. Y., was killed by being thrown from his buggy in a collision with a runaway farmer's wagon, on August 12th. Dr. Burneson was President of the Warren County Medical Society. He was seventy years of age, and had practised in Luzerne since 1854. He leaves a widow and one son.

Johns Hopkins University.—The appointments to the Medical Faculty of this University have recently been announced by President Gilman. The medical school will open on October 2d, and women students will be admitted on the same terms as men.

A New Hospital for Women.—It is said that a philanthropic lady of this city is negotiating for a plot of ground of the area of three ordinary lots upon which to erect a hospital for the accommodation of poor women suffering from diseases peculiar to their sex.

Human Remains for Refining Sugar.—A daily paper of this city published not long ago a despatch from Mexico in which it was stated that among the large shipments of bones from Mexico to the United States recently made for fertilizing and sugar-refining purposes, were ten car loads of human bones, said to have been obtained from ancient mounds in Southern Mexico, but more probably gathered from various old and abandoned cemeteries. As these bones are fragments from different skeletons, fifty thousand individuals are represented in the lot. The despatch doesn't say whether this particular shipment was designed for use as fertilizing material or for refining sugar.

Cost of the "Gold Cures."—The County Commissioners at Denver, Col., recently advertised for bids for treating the inebriates under their care, in accordance with a new law under which the commissioners are authorized to send indigent drunkards to some reputable gold cure institution. One institute offered to cure drunkards at the rate of $60 a head, and victims of the opium and kindred habits at $75. Another bid $33 per week, or offered to furnish the medicine at $20 and allow the county to attend to the patients. The Keeley-cure people bid $25 per week, while a fourth company desired to sell a formula for $500, and would instruct a physician in the art of using the medicine. The commissioners could not decide upon the merits of the different bids, so the indigent drunkards still get drunk when they can beg, borrow, or steal the wherewithal.

Dr. S. J. F. Miller, surgeon at the Soldiers' Home, Tongus, Me., died on August 7th, after a long illness, aged fifty-six. He served through the rebellion as surgeon of the Fifth Kentucky Infantry, and was in charge of the Loyal Legion Hospital at Louisville. After the war he practised in Cincinnati. He was superintendent of the Dayton, O., Insane Asylum, and surgeon of the Soldiers' Home at Milwaukee, and was transferred to Tongus six years ago.

The Tariff on Duelling in Russia.—Duelling in Russia has become so common that the Government has just decreed a severe code of punishment. Killing an antagonist will cost six years in prison: severe wounding, three years; duel without injury, six months; provoking a duel, six weeks to three months.

Mr. Ernest Hart and American Medicine.—Mr. Hart writes to the *British Medical Journal*: "I am returning from my short visit to the United States, as the guest of the American Medical Association, with a mind richly stored with pleasant memories and new impressions. The frank and cordial greetings of such large bodies of representative members of the profession from all parts of this vast continent, their self-respecting originality, their marked regional individuality, the friendly but distinctive competition for progress and leadership of North, South, East, and West, leave upon the mind a succession of vivid pictures which no words or anything short of observation can convey and impress New York with its wealth of clinical material, its largely developed hospitals and schools, and its prosperous practitioners and consultants, has a certain leadership which some think too self-confident, with its roots not yet deeply set. Boston cultivates with proud reserve and academic polish traditional thoroughness and a high university culture. But neither Boston nor New York were well represented at the Milwaukee Congress, from causes which have some interest beyond the American continent, and of which I propose to make a further study before undertaking to discuss them in detail. Before they can be removed—and all agree that in the interest of professional union they ought to be removed—some constitutional changes will be obviously needed. The present is rather a critical period in the development of professional life in America; there is a tendency to sectional caucussing and special 'congresses,' which is threatening to limit the usefulness of much scientific activity; it deprives the 'physicians,' the 'surgeons,' the 'laryngologists,' and so forth, of the power for good which comes from mutual and common intercourse, and the cultivation of a sense of unity and affection, amiable criticism, and common effort at the united congress, in which work is carried on in sections, but on one foundation. So much sectional difference has been aroused, and the organization of the annual sectional congresses all over the States has been so assiduously developed, that

some difficulty may be found in restoring unity of sentiment and action. Nowhere, however, could the results be more valuable than in America of a common understanding on the relations of the profession to the public and of their duties to each other. Nowhere does there exist a stronger need or a more useful sphere for medical thought and knowledge in guiding municipalities and executive officers in questions of public health and the government of public institutions, the endowment of science and the maintenance of adequate standards of education and examination. The future of the higher life in America and the development of culture and mental progress, the struggle against commercialism and the blinding and corrupting worship of the dollar, lies largely with the professional classes. The medical tradition is essentially a protest and an antidote against this curse of new communities. The most superficial observer from without must see that this great attribute of medicine and this high duty and privilege are recognized and brought into play in very different degrees in the various centres of the United States. The newest settlements and States are far from being the least developed in this respect. Chicago is laying wide and deep the foundations of its literary and scientific education. Two great and richly endowed public libraries—one with a limitless supply of medical literature—are already endowed with munificent incomes. The Rush College is of ancient fame, but is being largely extended; the Armour Institute and the Chicago University are springing into great efficiency and importance. Chicago has one of the best, if not the best, schools of pharmacy in America. Three thousand college students already throng her gates, and the munificence of her citizens is fast supplying them with solid and complete means of study and incitement to research. In the South, Baltimore has model institutes and typical hospitals to boast; Philadelphia, which aims at rivalling New York on a quite separate eminence, is not likely to be left behind. The Californian is the 'man of the future,' and is coming every year more to the front."

Very True.—The *Weekly Medical Review* says: "However, while we may look forward to great improvements in sanitary measures, keeping away epidemics which in former years have decimated nations, it will be impossible to say if the appearance of new diseases, more or less due to the effects of modern civilization, will not do what former epidemics have done, namely, remove from this world those individuals whose tissues are weakened to such an extent as not to be immune toward disease germs, or, if the latter have taken a foothold, to readily overcome an attack of disease."

Competition for a Hospital Position.—There is competition for hospital positions in Berlin which is even more keen than that in New York. The vacancy on the staff of the Moabit Hospital left vacant by the death of Dr. Guttmann has been filled by the appointment of Dr. Renvers, who was selected out of over fifty applicants.

A Curious Medico-Legal Contest.—On June 21, 1893, the case of Mrs. Margaret Powers *vs.* Dr. Dudley S. Reynolds, of Louisville, Ky., was decided in favor of Mrs. Powers, who had sued the doctor for a sum of money—the principal and interest together amounting to $4,584.73—which, she claimed, he had borrowed from her some thirty years ago, and had failed to repay. The defendant denied that he was the D. S. Reynolds involved in the borrowing, but did not succeed in convincing the jury to that effect.—*Medical Fortnightly.*

Phenduretin.—In the May number of the *Centralblatt für die gesammte Therapie* there is a summary, from the *Pharmaceutische Post*, of an article on this new phenol derivative that has been brought forward by a Csetnek apothecary named Orient. Mr. Orient describes phenduretin as forming fine, white, silky, acicular crystals that are tasteless, hardly soluble in cold water, and readily soluble in hot water. Its chemical constitution has not yet been determined with certainty. According to Mr. Orient's experiments on animals, it dissolves readily in the stomach and is absorbed into the blood within a short time. In large doses it appears to act upon the central nervous system and causes a profuse secretion of urine. A physician who has tried it in migraine is mentioned as having observed astonishingly good effects from it, coupled with its action as a powerful diuretic. The dose is from seven to fifteen grains, to be given twice a day.—*New York Medical Journal.*

Osteomalacia.—At the last meetings of various medical societies of Vienna different physicians gave their views respecting the frequency of the occurrence of osteomalacia. The chief symptoms of this disease in its latent stage, when it was liable to be mistaken for chronic myelitis, were stated to be pains in the limbs, over sensibility to pressure on the spinous processes of the vertebræ and on the iliac bones, and especially contracture of the abductors of the thighs. It was also stated that the disease was curable by the internal administration of phosphorus. One speaker said that he had observed recovery follow in one instance after a single administration of chloroform, while etherization was without effect.

The Paris Medical Faculty is sorely puzzled how to solve a problem that apparently is insoluble. While the number of medical students increases every year, the accommodation remains *in statu quo*, and the number of subjects for dissection decreases. Formerly the dead bodies of hospital patients, if not claimed by relations, were sent to the dissecting-room, but since the Municipal Council has accorded this right to friends of hospital patients there are much fewer subjects.

"**Pedology**" is a word of pleasant sound, and Dr. Emily V. Pardee evidently thinks it means the science of children's diseases. At least under this head she sings these stanzas, which have a Browning beginning and a medicinal finale:

"Do you hear the children crying, O my brothers,
Ere their sorrow comes with years?
They are leaning their young heads against their mothers,
And *that* cannot stop their tears.

"Do you question why they have such sad and sunken faces,
Why they weep so bitterly?
'Tis because the old-school doctor tends their cases
And they never tasted Homœopathy."

One of the Judges of this city is reported to have declared that he would not commit anyone to an insane asylum simply on the certificate of two physicians, and that hereafter he would have to see the patient.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Sixty-first Annual Meeting, held at Newcastle-on-Tyne, August 1, 2, 3, 4, and 5, 1893.

(Special Report to the MEDICAL RECORD.)

First Day, Tuesday, August 1st.

The proceedings commenced on Tuesday morning with a meeting of the Council, which was private. But at eleven o'clock the first general meeting was held, when the report of the Council and reports of several committees were submitted and adopted. These reports had already been printed, so that each could be digested by those specially interested in them. It must be acknowledged, however, that in the time at the disposal of members it is impossible to deal with the many important subjects comprised. Consequently, such discussion as time permits is desultory and often confined to side issues or minor points. It is regretted by many members that no adequate criticism can take place, and in its absence the reports can only command the respect due to the several committees, and ought not, although accepted at general meetings, to be put forth as the expressions of opinion of the Association. Some of them, there can be no doubt, would be found to excite considerable opposition. The report of the Council mentioned that several of its members intended visiting the Chicago Exhibition, and had been requested to represent the Association at the various congresses.

The Treasurer's Report stated that the revenue for the year was £34,143; expenditure, £29,122. The balance, of about £5,000, had been invested, raising the amount of investments to £37,000. The excess of assets over liabilities was stated as £50,735. Mr. Butlin was re-elected treasurer.

Address of Welcome. — The Mayor of Newcastle inaugurated the evening session by gracefully welcoming the members to Newcastle, stating some of its objects of medical interest, and testifying to the esteem in which the President, Professor Phillipson, was held by his fellow-citizens. Dr. Phillipson thanked the Mayor and Corporation in a few appropriate words, and afterward specially invited Professor Pozzi, as representing France, and Professor Giampietro, as representing Italy, to come to the platform. Representatives of colonial branches also received a cordial welcome, after which the

Presidential Address.—After some introductory observations on the growth of the Association and of the town since the first meeting in Newcastle twenty-three years ago, Dr. Phillipson followed the example of many predecessors in giving a sketch of the locality in which the meeting was held. The origin of Newcastle, he said, was due to the Romans. The municipal history of the town dates from Henry I., and the formal list of mayors begins in 1251. The College of Medicine and the College of Science were then referred to, both being colleges in the University of Durham, which was opened in 1833. The Literary and Philosophical Society, the Natural History Society, the Antiquarian, Geographical, Medical, and Clinical Societies were next mentioned, and then the Royal Infirmary and other hospitals and medical institutions.

Diseases of the Locality.—The speaker then took up the subject of the diseases specially prevalent in Newcastle. In the three northern counties he estimated the number of people employed by the coal mines at 120,000, and notwithstanding the character of the work he said there are but few diseases peculiar to miners.

Anthracosis is very rare, he said. Emphysema occasionally occurs. Pitman's asthma is well known, but less common than formerly. Miners are also very exempt from nephritis, due to the profuse perspiration when at work, and the ablution they practise on going home. Rheumatic affections are also rare, due to the same causes, although the work in heated atmosphere, in currents of air, often in damp and wet places, might be expected to produce them. The miners of the North of England enjoy an average of three years longer life than the aggregate of Englishmen, eight years longer than Cornish miners, nine longer than South Wales miners, and only one less than the healthiest districts of the kingdom. The frequent occurrence of diseases of the cardiac, vascular, and nervous systems was noted. Workers in iron suffered from diseases of the heart and aorta, owing to the strain on the blood-vessels. In the past five years fifteen per cent. of the medical cases in the Infirmary were diseases of the circulatory system, and of these 15.6 per cent. were of the great vessels. There are large lead-works on the Tyne, and the Infirmary is rarely without several cases of lead-poisoning in the wards. Women suffer more from this than men, as they are employed in handling and packing the carbonate. The Home Office has appointed a commission to inquire into the sacrifice of life in the manufacture of white and red lead, and the conditions under which the process might be safe. Cholera has been epidemic in Newcastle on three occasions, in 1831–2, 1848–9, and 1858. In September, 1892, one case was brought from Hamburg, but there was no spread of the infection. The mortality in 1871–80 was 25.8. In the next decade it was 23.6, a fall of 2.2. During the same periods there was a fall of 1.6 in the seven chief zymotic diseases. The President next spoke of the notification of diseases, of which he has long been an advocate, and he suggested that it should be everywhere compulsory, and that the county councils might utilize the information collected; but these bodies, he admitted, had hitherto been very apathetic, and only a few had appointed medical officers of health. Parliament has left county councils to define the duties of such officers, so that they may fulfil such duties as are now performed by the central staff in London. In this appears the true spirit of decentralization. Advice from a body directly connected with the community to which it is given, will be more readily acted upon than if it came from a central body or official.

Pollution of Rivers. —Dr. Phillipson then took up the subject of the "Pollution of Rivers," and said river inspection is an urgent necessity from a sanitary as well as an economical point of view. From the former, river waters have been rendered undrinkable by man and animals, a nuisance in some places, from manufactories, or from sewage and dangerous carriers of disease. From the economical aspect, pollution has destroyed the fish. The subject was dealt with by Parliament in 1388, and now, after the lapse of five centuries, again engrosses the attention of sanitary authorities and experts.

The recent lunacy legislation, he said, is of importance. The Acts embodied an attempt to combine protection to the public, the lunatic, and the liberty of the subject, with some protection to medical men whose duty it was to discharge various difficult duties toward the insane. The protection of medical men proves, however, so inadequate in practice that many are very averse to signing the certificates.

A Minister of Public Health.—Although sanitation is more advanced in this country than elsewhere, it must not be forgotten that much remains to be done. Legislation having aimed at throwing all the burden for providing for public health on local authorities, had not insisted that they shall respect and practise the regulations laid down for their guidance. It is true that the approach of cholera had led to a survey of the chief ports, but such work should not be confined to our first line of defence, but extend to the fifteen hundred areas into which our sanitary defence was split up, without in any way lessening the responsibilities of local authorities. This survey should be undertaken by the central government. The great need of our system was a closer touch between the local and central authorities, and for this a Minister of Public Health was urgently needed. Such a minister, selected for his transcendent professional abilities, and not for his political bias, would save an enormous amount of

delay, vacillation, and disagreement on sanitary subjects, and tend to raise the status of the profession. Very little could be expected from legislation, until the legislators were assisted and instructed by experts. Good laws could only be applied and their effects insured by well-qualified agents acting under one responsible head.

The address, which occupied about an hour, was listened to with attention by the crowded audience, and elicited much applause. A vote of thanks, proposed by Sir D. Duckworth and seconded by Dr. Ord, was carried with applause, and the President briefly returned thanks for the manner in which his address had been received.

The Reports of the Committees on Inebriates Legislation, Medical Charities, Railway Servants' Eyesight, Physical and Mental Condition of School Children, were severally proposed, seconded, and agreed to. A new by law was also enacted, providing that any member whose name had been removed from the Medical Register should thereby cease to be a member of the Association, but should be eligible for re-election in the event of his name being restored to the Medical Register.

SECOND DAY, WEDNESDAY, AUGUST 2D.

A general meeting was held in the afternoon, when the Ex-President, Mr. Joseph White, was elected a Vice-President for life: it was announced that the Council had chosen Dr. Ward Cousins as President of the Council for the next three years, and a vote of thanks was accorded to Dr. Withers Moore for his services in this capacity during the past three years.

Dr. Ward Cousins then announced that the Council had received a cordial invitation to hold next year's meeting at Bristol, and that they had agreed to accept this invitation, and nominated Dr. Long Fox as president-elect. This recommendation was unanimously confirmed. Dr Fox thanked the Association for the honor done him, said the whole profession at Bristol would welcome the Association, and prophesied that the intellectual portion of their meeting next year would be worthy of the metropolis of the Southwest.

Causal Relations in Disease.—The address in medicine was then delivered by DR. DAVID DRUMMOND, of Newcastle. After some introductory observations and references to the backwardness of pathology and the effects of terminology, Dr. Drummond took up the subject proper of his address, asking if it would not be an advantage to take a leaf from the chapter of experimental pathology and endeavor to show that disease may with more justice be referred to one cause than to several.

Illustrations of Unal Causation.—The speaker then proceeded to test the practical bearing of this theory by a brief examination of a few of the more prominent morbid conditions whose claim to belong to the category of diseases having a constant cause is pressing. In this class he included the relation between syphilis and locomotor ataxy. He regarded locomotor ataxy as invariably the result of antecedent syphilis, and held that (some statistics notwithstanding) where the former is found one may declare with a feeling of absolute certainty that there has been at a previous date the latter, to which this locomotor ataxy is in some manner due. Gowers says that syphilis is not the only cause of the disease, and that "in a few cases (less than ten per cent. of the whole) it can be excluded with confidence." The speaker ventured to question this opinion, and asked whether we ought to wait until in 100 per cent. of cases locomotor ataxy can be unerringly traced to this cause, before we believe in the inductive force of the ninety odd per cent. Such a course would be a virtual expulsion from medicine of the inductive method, which has hitherto been its best friend and its glory. This method does not profess to deal with every conceivable case, but only with such a number as may legitimately command assent and establish confidence, and is, with its results, valueless if we may not reason from such a large majority to the whole. It would be an interesting experiment to try to ascertain how much of the "less than ten per cent." would remain if the patient who gives evidence could be guaranteed a good memory, and indemnified against the penalty which a true record might entail.

Another disease which Dr. Drummond ascribed to the same specific factor is general paralysis of the insane. Here the burden of proof is attended with still greater difficulties to the statistician, who has in many instances to deal with patients whom Nature in robbing of past memories has deprived of the ability, if they possessed the will, to furnish a true record. And further, among general paralytics we find a larger proportion of women than among tabetic cases—a fact which lends an additional complication to the case. Notwithstanding these obstacles, we find that one of the most recent declarations (Jacobson, *Journal of Mental Science*, April, 1892), goes so far as to claim that at least sixty-five per cent. of the cases are specific, and we know that years ago Steenberg and others contended for the unal theory, namely, that there was "no general paralysis without syphilis." If further evidence were required in support of the theory of the constant connection between syphilis and general paralysis of the insane, over and above that furnished by statistics and interpreted in the light of the inductive method of reasoning, it is to be found in the fact that this disease is virtually the only progressive mental disease with which we are familiar, with a definite and recognizable anatomical lesion. And this fact alone justifies us in pronouncing in favor of a special causation, for it singles out the disease, and seems to warrant the conclusion that, as a definite pathological process has been at work, so has there also been a special etiological factor. He believed much might be done in those diseases by specific treatment, if instituted early enough, and indeed it is impossible to say how many cases of locomotor ataxy and general paralysis have been prevented by the timely use of antisyphilitic remedies, when at the outset a clew is forthcoming.

The Relation of Aneurism to Syphilis.—For many years the speaker had been deeply interested in the study of the connection between syphilis and aneurism, and in common with others has been struck with the frequency with which the former occupied a prominent place in the history of a sacculated aneurism. Since commencing the investigation no indisputable case has come under his notice in which specific disease was wanting, excepting two or three examples of acute softening of the arterial wall, with aneurismal bulging, in malignant endocarditis. Arterial strain through hard work is of course a factor in the production of aneurism, but it is one that in the vast majority of instances requires to be multiplied by specific arteritis in order that the product be aneurism, and then it is the lesser quantity of the two

The Relation of Empyema to Pneumonia.—The causal relation of pneumonia to empyema, one of the closest if not the most constant, the latest text-books notwithstanding, is another exemplification of the subject. True there are cases of pus in the pleural cavity that have not arisen out of an attack of pleuro-pneumonia, due possibly to an acute septic pleurisy, or to tuberculous pneumothorax, or as the result of a simple effusion becoming contaminated by septic matter, say by means of a trocar, but these are exceptions. Exclude them, and it may fairly be concluded that empyema, the common disease with which practitioners are so familiar, may be ascribed to an antecedent pneumonia.

The Relation of Chorea and Rheumatism.—Few subjects have excited more interest than the relation between rheumatism and chorea, and none has occasioned greater divergency of opinion. It may be said that the present state of our knowledge does not warrant a consensus of opinion. That may be true, but it is no reason why, out of our present knowledge, a theory should not be advanced in thorough harmony with well-ascertained facts, which may at any rate be a guide to fuller revelations, with increase of information. If it be admitted that a certain proportion of cases of chorea are associated

with rheumatism, the inquiry naturally divides itself into two parts, the nature and extent of the relationship. The speaker's own cases greatly favored the idea of a frequent and close connection between the two, so much so that he was inclined to the view that, in a certain proportion at least, chorea is simply one manifestation of the disturbance by the rheumatic poison of the function of somewhat unstable and growing cortical cells; and if this conception be tenable in a few instances, may it not, he said, be extended so as to include the whole of the familiar group of typical choreic cases so common among the children of nervous and rheumatic families, and prone to yield to large doses of arsenic?

The Causation of Cardiac Disease.—The study of cardiac lesions throws into relief the importance of tracing diseases to their true causes. They are all referable to primary conditions—rheumatism, gout, specific fevers, tuberculosis, sepsis, alcoholic excess, syphilis, etc., which are singularly fruitful in morbid products. These conditions constitute a formidable list, to which we are constantly adding, and each is responsible for heart affections having more or less characteristic clinical and pathological features. The immense importance of investigating cardiac diseases upon the basis of their antecedent and underlying morbid states cannot be over-estimated, for the treatment and prognosis depend largely upon the particular agent at work. It has been the habit of our schools to attach too much value to the diagnosis of the particular valve lesion, and too little to its cause. Thus, for example, we content ourselves with the shallow and often unimportant observation that this or that case is one of mitral regurgitation or double aortic disease, forgetful that what is of paramount importance is not only the primary reason for the existence of the lesion, but also the cause upon which the symptoms belonging to any subsequent attack of cardiac failure may depend. Thus the inquiry would necessarily embrace the questions in the case of toxæmic lesions—gouty, rheumatic, alcoholic, etc.—is the poison still circulating? and what is the prospect of its return? Difficult, and at present more or less problematical, are these questions, but to them we must direct our attention before we can hope to prognose and treat heart disease successfully.

Would a substantial reduction in the number of chronic heart cases, as the result of the recognition of the fact that many are due to curable and preventable causes which an early and successful treatment might reasonably be expected to subdue, be a dream too visionary for us to indulge in? Dr. Drummond thought not; but assuredly until we fully appreciate the causes a dream it will remain.

The Modifying Influence of one Disease upon Another.—The speaker then took up the question of the modifying or controlling influence exercised by one disease upon another, and even in this enlarged sphere of inquiry we walk by the light of this principle of causation.

Familiar clinical pictures of disease of an organ are often, he said, the product of the symptoms peculiar to it, and of others which are the expression of impaired function of another organ. In other words, the full symptom-complex of disease of one organ may be largely contributed to by disease of another, whether produced by the same or some other cause. He illustrated his meaning by an example. A patient addicted to alcoholic excess for a considerable number of years is known to be suffering from a group of dyspeptic symptoms, ascribed by the patient, friends, and doctor to this cause, but without a suspicion of gross organic mischief underlying them. This state of health interfered but slightly with the discharge of public and private duties, and indeed, beyond loss of flesh and some discomfort, there was a complete absence of signs of disease. An attack of pneumonia, which tried his powers of endurance considerably, and was followed by a slow convalescence, completely altered the character of the case. Within a fortnight or three weeks of the incidence of the pulmonary disorder, the abdomen swelled and its superficial veins enlarged, the lips became red and the tongue glazed and red, the face pinched, and the urine scanty and full of urates, the motions black, and in every way a most suggestive picture of cirrhosis of the liver was presented, a transformation that astonished the doctor and friends, and was not at first sight easily explained. The other reasonable assumption to account for the apparently rapid development of cirrhosis of the liver was, that the disease had existed for a considerable period in a latent form, and that the obstructed portal circulation was compensated for by the usual auxiliary relief, which served to reduce congestion, and thus keep in check the tendency to ascites, etc., until the attack of pneumonia, by producing cardiac insufficiency, upset the balance, and led to the appearance of the typical signs hitherto absent. Let us observe that, though the pathological changes characteristic of cirrhosis were present, the clinical aspect of the case was incomplete until a new and necessary factor, which had nothing to do with the original disorder, revealed the true nature of the illness. It seems a just inference that the cardiac affection made an important, if not essential, contribution to the completion of the symptom-picture.

But it is not enough to say that clinical pictures may be the joint products of symptomatic morbid relations, for they are often presented to us under the modifying influence of a tendency or bias, lent by a former or a concurrent disease; that is to say, it is quite common to meet with pronounced modifications in the clinical pictures of disease which can only be accounted for on the principle that one disease has a determining influence upon the aspect of another. For example: A man in the prime of life, who was much addicted to alcohol, came under observation for complete double drop-wrist, presenting every feature of a plumbic case. His history revealed the fact that twelve years previously he had suffered from lead palsy, with blue line, the result of drinking contaminated water, and as he was recovering he acquired intemperate habits, and developed into a chronic toper. The consequence was that the paralysis of the extensors became more pronounced, and remained permanent. There was absolutely no paralysis of the lower extremities, and the knee-jerk was normal.

The modifying influence of one lesion upon another may be decidedly beneficial. Thus, sarcoma and lupus may yield to the poison of erysipelas; of which fact, it is reasonable to suppose, more will be made in the immediate future. The controlling effect of disease on disease is also to be seen in the fact that it is quite rare for pulmonary tuberculosis to spring up in the course of a cardiac affection. And, again, it is not unusual when lardaceous disease develops in consequence of chronic phthisis, to observe a distinct tendency on the part of the tubercle to be arrested in its growth. And, further, in this connection the speaker said that he had been struck with the rareness with which a pneumonia complicated with jaundice proves fatal.

In concluding, Dr. Drummond said that the main aim of his address had been to arouse and quicken an interest in the study of morbid relations, wherein our success will much depend on our having a ruling principle for our guide, and a definite object and end in view. An inquiry into the symptoms, diagnosis, prognosis, and treatment of disease cannot fail to be greatly facilitated by keeping ever before us the particular cause or causes at work in producing an uncomplicated disease, or in furnishing the kaleidoscope aspects of many of our cases. In one way it seems a work of supererogation to inculcate the close observance of causes: for, as a rule, the practitioner gradually comes to perceive its importance, and automatically seeks for the cause, and is satisfied only when he has found it; and that he may register his observations he is driven to an accurate system of nomenclature, which shall possess for him both an etiological and a diagnostic value. Every advance in this direction is a positive gain to medicine: and whether we succeed in tracing a disease to its true origin, or attempt the more

arduous task of disentangling the morbid web with a view of assigning its due proportion of responsibility to each factor, and so of dealing with the whole, we are engaged in the employment of a method which, if developed, may make a revolution both in the name and treatment of diseases

On the motion of Dr. Ord, seconded by Dr. Byrom Bramwell, a cordial vote of thanks was accorded to Dr. Drummond for his admirable address.

The report of the Committee on Anæsthetics was adopted.

Admission of Women to the Association.—Dr. Galton then proposed an alteration in the By-laws which would remove all restrictions on the admission of qualified medical women as members of the Association. The resolution was seconded by Mrs. Garrett Anderson, M.D., and carried *nem. con.*, and not without applause.

The question of payment of travelling expenses to members of council, which has several times been before the Association, was then again brought forward. This question in various forms has been before the Association several times and threatens to be again and again. Certain members seems to find it interesting, but very few care about it. It was resolved to continue the present system by a show of hands of 17 against 6, the members having mostly rushed away at the conclusion of the address.

A large number went to a garden party given by the sheriff. The weather was bright, the music cheerful, the ground very pretty and the hospitality hearty.

Third Day, Thursday, August 3d.

The morning of this day was devoted to the Sectional proceedings. In the afternoon another general meeting was held.

The Evolution of Surgical Principles was the title of the address in surgery, delivered by Dr. G. H. Hume, of Newcastle-on-Tyne. The "principles of surgery" is one of those elastic phrases which carry to our minds a fairly exact meaning, but to which we find it hard to give a concise definition. We certainly do not use it as the equivalent of theory, but yet theories which become the motive or suggestion of surgical action are surgical principles, and these may be sound or unsound according to the character of the views upon which they are based. The mode of formation of surgical principles is a double one. They may arise like a superstructure upon a foundation of scientific knowledge, or they grow down out of experience to be themselves part of the foundation. They are the mainsprings of action; and so far from being alien to practical efficiency, they are at once its inspiration and guide.

The mode of growth of scientific principles can find no better illustration than in our modern doctrines of surgical repair. The beginnings of these doctrines may be traced far back in the history of surgery. But it was by Hunter's work that the real beginning was made. His statement that "primary healing takes place without inflammation" contains the germ of what we believe and act upon now. It did not, of course, go far enough. It defined the relationship between what was then, as it is now, ideal healing and inflammation, in the sense that no relationship can or does exist between them at all. But, notwithstanding this gleam of light the subject remained obscure, and down to a recent period the ideas of healing and the ideas of inflammation seemed in the very nature of things to be inseparably interwoven. It turns out that they were only needlessly entangled, and ideas which in the time of their confusion belonged mainly to the region of theory have since proved to be matters of the most eminent practical importance. The process of disentangling began in and proceeded with the elucidation of the true nature of inflammation and its consequent suppuration. There was a time when the four classical symptoms of pain, heat, redness, and swelling, summed up nearly all that was known of the process of inflammation. Then followed the anatomical era, in which attention was concentrated on the blood stasis, the changes in the tissues and in the vessel walls, and on the out wandering of the white corpuscles. An intermediate stage followed this, in which, clinically and experimentally, the suppurative processes were recognized to be infective in their nature. And this culminated in the period in which we now find ourselves, when the whole process is demonstrated to be due to the agency of micro-organisms.

We have now gone back to Hunter's dictum, only we have given it a more extended, or rather, an unrestricted, application. The surgeon's part, therefore, is now not to treat but to prevent inflammation and suppuration, and the practical side of the scientific evolution I have briefly sketched is the antiseptic system.

It has sometimes been made a reproach against the system of wound treatment by the introduction of which Lister created an epoch in surgery that its methods and details have undergone constant change. But through all the alterations of detail, there has been no deviation of principle. The dependence of suppuration and septic diseases upon organisms, and the prevention of these diseases by destroying or getting rid of the cause, is the principle on which the treatment rests, and it is one which admits of some latitude in its application. The aim can be achieved in two ways. Either reliance is placed mainly on the germicidal powers of chemical agents, or the surgeon prefers to trust rather to the removal of the minute organisms along with the soil in which they flourish. The two roads to the same end we know under the names antiseptic and aseptic; and fortunately we are able in this case to travel on both at the same time. So far as our work is concerned, we have thoroughly learned the lesson that cleanliness takes no second place, that it is the highest virtue in surgery.

Those of us who have worked through the whole of the antiseptic period can in looking back trace with some interest the different phases through which the method has passed. The main changes in the *technique* of the treatment have owed their origin to changing views as to the sources whence danger of infection might be expected to arise. The aim was at first to avoid atmospheric contamination; hence we had sealed wounds, and later the spray. Gradually the belief strengthened that our own hands and the skin of the patient, besides the instruments and sponges, which had always been cared for, were most often at fault; and as a result even the most orthodox believers in the potency of carbolic acid or corrosive sublimate became scrupulous cleansers.

No one now is ever heard to speak of laudable pus; no pus is considered praiseworthy; but, on the contrary, if it appear in a wound for which the surgeon is responsible, and in making which he had the control of all the conditions, it is always a thing to be ashamed of. Healing without suppuration, therefore, is the end aimed at in all operation wounds, and in a sense it is an extended description of union by first intention. It applies to wounds healing by granulation, or by the organization of a blood clot, as well as to those uniting by primary adhesion.

From trusting more, because knowing better, Nature's powers of repair, it has followed that the range of reparative surgery has been greatly widened. It is not now thought sufficient in bringing wounds together to pass our sutures through all the tissues at once, but each layer is separately stitched—muscle to muscle, fascia to fascia, skin to skin This is one of the lessons which, if it did not at first teach us, abdominal surgery has been forward to utilize. The gain in abdominal operations is in a greatly strengthened cicatrix and the avoidance of ventral hernia. In general surgery the gain is in promoting healing by the obliteration of "dead spaces," and the consequent less frequent need of drainage.

Skin grafting, according to the method of M. Reverdin, has long been a valued resource in hastening the cicatrization of granulating surfaces. But the method

known by the name of Thiersch makes larger demands on tissue vitality, and is of wider usefulness. When a portion of the skin—it may be as large as an inch square—is detached and transferred to a recent and aseptic wound, it retains its inherent vitality until it becomes penetrated by blood-vessels advancing into it from its new bed. It is thus fully adopted and incorporated in its new position. As if to explain the eager readiness with which the vessels and proliferating cells of the wound surface enter into and constitute an organic union with the new part, Thiersch has advanced one of those theories which, whether they prove in the long run to be well or ill founded, give by their aptness a special kind of mental satisfaction. By a legitimate scientific use of the imagination he supposes that a store of proliferating energy exists in the tissues which, in their intact condition, is kept in check by the mutual pressure of their elements. The constituents of the tissues, in other words, do not grow beyond a certain point for want of elbow room; but when this mutually restraining pressure is removed by a breach of surface their proliferating energy is set free, and by their liberated activity they become competent to carry out the work of repair. It is not necessary in removing the graft to take the whole thickness of the true skin. A portion of the corium left behind will, by obviating cicatrical contraction, lessen the sacrifice for that surface which is the donor, without diminishing the value of the gift to the recipient. In plastic operations on the face, and in operations for malignant disease which have involved free removal of skin, the method has found useful application.

One of the most useful applications of skin-grafting is in the treatment of ulcers of the leg. Bearing in mind the necessity of an aseptic condition of the bed upon which the grafts are to be placed, it is requisite, by paring the edges, and by thorough scraping of the surface with the sharp spoon, as well as by the use of antiseptic solutions, to surgically cleanse the ulcer. To get rid of the irritating effects of the antiseptics, they should be washed away by sterilized water before the application of the grafts. So treated, an ulcer is brought into the condition of a recently made wound, and success entirely depends on the thoroughness with which this transformation can be effected.

In the grafting and reimplanting of bone the incorporation takes place, no doubt, in the same manner as in the skin. We have learned, also, that the breaking up of the bone into small chips is not always necessary; at least that it is not necessary in the case of the disks removed in trephining the skull. Provided these be of moderate size, they can be replaced whole.

In the direct suturing of the divided ends of nerves it may be supposed that immediate reunion of axis cylinders with restoration of function may take place. But when a graft several inches in length is interposed between the widely separated nerve ends, and sensation returns in thirty-six hours, what is the anatomical and physiological condition of the graft? Can it have become so vascularized, and have its axis cylinders acquired such intimate union with those of the nerve ends as to make it in so short a time capable of conducting impressions? The subject appears to call for further investigation.

Tuberculosis.—Before the microbic origin of tubercle was known surgery was becoming more aggressive in the treatment of so-called scrofulous disease. But from the new light the surgery of tubercle has gained immense encouragement. The theory of a constitutional origin has been changed into the belief in a constitutional vulnerability; and, now the surgeon undertakes the treatment of local manifestations of tubercle by local measures. In consequence the surgery of tubercle has undergone great extension. Affections of the skin, of the glands, of the bones and joints, of the urinary organs, of the peritoneum, are submitted to local treatment. And the extension has been in the direction not only of new applications, but of greater thoroughness. The knowledge of the infective character of the disease, and of the liability to local relapses, or even general infection as a consequence of incomplete removal, has led, for example, to the excision of every affected gland or of every diseased focus in a joint. And the guidance afforded by pathological knowledge is even more explicit with regard to other points of treatment. The important question of general infection has light thrown upon it by what we know of Nature's endeavors to imprison by a wall of granulation tissue a tuberculous focus. When by an incomplete operation we break down this wall or cause it to crumble by infecting it with pus microbes, without entirely removing the tuberculous disease, we open the way for the passage of the tubercle bacilli into the system. Hence the extreme necessity of keeping our operations free from sepsis, as well as of making them thorough.

Cancer.—The whole disease picture presented by cancer offers so many points of resemblance to that of tubercle, that the probability of a parasitic origin of it also has at present taken strong possession of the minds of pathologists. The occurrence of minute organisms of the class of sporozoaria in connection with cancer has, the speaker held, been demonstrated; but any causal relationship between them and the disease has not been proved. We have as yet nothing beyond the nature of conjecture as to the essential cause of cancer; and as to many facts of secondary, but still great, importance in the natural history of the disease, we have to own that our knowledge is so vague as to be little better than ignorance. On one point of importance there is agreement and a growing readiness to act upon it. Due largely to the influence of Mr. Jonathan Hutchinson, a precancerous stage of cancer is recognized; and it follows from the recognition that surgery ought to interfere during this period of suspicion. Another point of practical moment is brought out by the observations of Dr. Sims Woodhead and Mr. Harold Stiles on the channels of lymphatic infection, in which it has been shown that whenever irritative or effete material has to be dealt with in large amount a special filtering tissue is developed. This, which consists of a growth of adenoid material, is formed in the connective tissue along the lymph channels, and is produced still more strikingly by the transformation of the small lobules of fat in the axilla. One of the great difficulties of dealing with cancerous disease is that we have no means of knowing when lymphatic infection first takes place. As the lymph circulation is always going on there is no reason why infection may not occur in the very earliest stage of the primary growth. In dealing with cancer, therefore, we are meeting an enemy whose first invasion is invisible, and whose strength at any time we cannot even guess at; but all we know of its nature only points to the necessity of free removal. Dr. Hume said that his own experience was strongly in favor of the removal of the next group of glands along with the primary cancer, whether they show gross enlargement or not. To no subject in the whole range of medicine has there been devoted a greater patience in observation, a more continuous labor in inquiry than to the subject of cancer. The hope of now solving the problem by demonstrating its parasitic origin has enlisted a fresh band of workers whose skill and tenacity in their investigations will surely lead to some definite result.

The speaker then referred to advances in surgery which had come from a revised reading of certain facts in topographical anatomy. In illustration of these he spoke of the rapid creation of the surgery of the cæcum and appendix, and the revival for the high operation for stone.

Canons in Surgery.—There is a large body of surgical principles which spring almost purely from observation and experience. In this sense of principles derived from experience Dr. Hume used the word as implying not a fundamental fact in science on which action is based, but a rule of action adopted because it has been found, or thought to be, the best, and stamped with the authority of general acceptance. The phrase "canons in surgery," used long ago by John Bell, and revived a few years ago by Mr. Hutchinson, very aptly covers these rules of experience. Their character and mode of formation will be best

shown by an example. The question of amputation in senile and diabetic gangrene of the foot seems to be in course of settlement, in favor of operation. The condition is almost certainly fatal, and is fatal often after a period of lingering and intense suffering. As a measure for its relief or for the saving of life, amputation has almost uniformly failed when it has been done in the lower part of the leg. The gangrene seizes upon the flaps, and if the limb be reamputated higher up the stump is again attacked. But it has been found that if the leg be taken off in the first instance above the knee a fair proportion of cases recover. About one-half, according to the most recently collected figures, have been successful, and in a condition so hopeless and usually so painful, such a result is better than the certain issue of non interference.

An old and familiar surgical canon, formulated by our predecessors as a result of experience, enjoined on the surgeon the duty of operating, "when in doubt," in all cases of hernia. We greatly need the guidance of some equally definite rule in cases of internal obstruction. Upon the question of operation surgeons are, if not divided into two parties, at least biassed in contrary directions. Some would operate in all cases of complete obstruction so soon as they have the opportunity; others would try other measures, see what Nature will do, and operate as a last resource. And strong arguments are to be found on either side. Where are we to look for guidance? Mainly, the question must be settled by experience; it is a case to which the maxim "Solvitur ambulando" applies; and experience will aid by bringing to us the ability better to discriminate between the different causes producing obstruction, and to appreciate the prognosis to be attached to each.

Shock.—In concluding, the speaker dwelt upon the duty of the surgeon to avoid, or as far as possible to minimize, shock. We do not know the exact pathology of the condition; probably several different conditions are included under the name. But we are very familiar with its symptoms. We know that the patient becomes cold, that the heart's action is depressed, and that all the nervous functions are lowered. We know also that it is induced or aggravated by prolonged operation, by chilling of the surface, by hemorrhage, whether this take place rapidly or by continuous oozing in small quantity for a long time. The giving of chloroform on successive days lowers the patient's resisting power. All this supplies hints enough for its prevention and treatment. Something can be done in anticipation of the operation in the way of propping both the physical and moral courage of the patient. Much can be done after the operation in rallying from the condition: and Dr. Hume believed that a very small, stimulating, hypodermic dose of morphine has proved then of greater use than the same measure employed as a prophylactic. Transfusion with normal saline solution has a wonderful power of rallying from shock, but in the speaker's experience its good effect is disappointingly transitory. But most is in our power in the way of prevention by guarding our patients against all those causes which produce shock or aggravate it.

A cordial vote of thanks was given to Dr. Hume for his address.

Dr. Armstrong, the medical officer of health, conducted a number of the members over the temporary cholera hospital.

Opening of the New Home for Incurables.—The ceremonies of the opening of this home, which has just been completed by the Corporation, then took place. It was delightfully fine weather, and upon the lawn in front of the new building a dais had been erected, in front of which seats were placed for visitors. The lawn is bordered by flower-beds and groups of trees, and the grounds are beautifully laid out. The Chairman of the Charities Committee of the Corporation presented a golden key to the Mayoress, and also a silver lamp as a memento. The lady made a pretty speech in reply and duly applied the key to open the building, which provides accommotion for forty-eight cases besides twenty of a cancerous nature.

Dr. Phillipson, as President, expressed his thanks for the invitation to the British Medical Association to be present, and said no gathering could have been more appropriate. Many of the visitors then inspected the wards, where a sale of work was held, which was freely patronized. It was said that many of the articles were made by the inmates.

The Public Dinner of the Association—always a great function with many—was held in the evening. The President occupied the chair and was supported by the Mayor, the Recorder, and other prominent citizens of Newcastle. Lord Armstrong, in responding to the House of Lords, made a pleasant little speech, and the Recorder, Sir Digby Seymour, Q. C., was intrusted with the toast of the evening, to which he did full justice. The speeches of the officials of the Association were as enthusiastic as usual, but rather wearisome to habitués of these meetings. as one seems to have heard them so often before.

The first of the excursions also took place on this day. This was to Tynemouth, where the Mayor and Corporation entertained a party of some five hundred ladies and gentlemen to luncheon. Tynemouth has been called the Brighton of the North, and is a very pleasant and healthful resort, with beautiful sea and land views, an interesting history, and ancient relics.

Fourth Day, Friday, August 4th.

The sections again devoted two hours to their work, after which followed the concluding general meeting, at which Dr. C. J. Cullingworth delivered his address on "Obstetrics and Gynecology," of which the following is a brief abstract.

Pelvic Peritonitis and the Pathological Importance of the Fallopian Tubes in Connection Therewith.—Dr. Cullingworth reviewed at some length the history of pelvic inflammation, dwelling especially upon the work of Bernutz in this line, and then discussed the subject as it is understood to-day.

Pelvic Cellulitis Commonly a Secondary Disorder.—During the past five or six years the speaker said he had performed abdominal section in nearly one hundred cases that in the earlier part of his professional career he would have regarded as well-marked examples of pelvic cellulitis, namely, cases in which the mobility of the uterus was more or less impaired, and in which hard, irregular, fixed swellings could be felt above one or both lateral fornices of the vagina, and often extending into Douglas's pouch. In the vast majority of those cases he found no evidence of cellulitis at all, and, where it did exist, it was clearly secondary to the salpingitis and peritonitis which constituted the principal lesions present. In no case was there any inflammatory exudation in the cellular tissue of the broad ligament or elsewhere sufficient to form a distinct tumor recognizable as such on bimanual examination. In some cases of chronic suppurative inflammation of the uterine appendages, the broad ligaments were the seat of a certain amount of thickening from inflammatory exudation, but this obtained only in the neighborhood of the suppurative disease, and the thickening seldom exceeded one-eighth of an inch, and even in extreme cases never exceeded half an inch.

Pelvic Inflammation Usually a Peritonitis Originating in Salpingitis.—The usual state of things disclosed on opening the abdomen in these cases is as follows: The contents of the pelvis are generally concealed from view by the great omentum, which has been drawn down so as to cover them in anteriorly, and has contracted adhesions to the peritoneum as it becomes reflected on to the anterior abdominal wall, as well as to the uterus and other pelvic viscera. Along with this screen, as it were, of omentum it is not unusual to find coils of adherent small intestine. On separating and drawing aside this screen, one side, or it may be the whole, of the posterior part of

the true pelvis is seen to be occupied by what appears to be an indistinguishable mass of matted viscera. The uterus itself is sometimes implicated in the mass, but in other cases its upper part at least is free. Tracing the Fallopian tube outward from the uterine cornu on the side of the disease, it is often found to be normal in size for the first half-inch or so, and then to become involved in the adherent mass. This mass, on being separated and brought into view, is invariably found to consist of the uterine appendages more or less altered by inflammation. There is always salpingitis, and the inflamed and thickened tube usually enfolds the ovary. In a large number of cases the ovary itself is normal, except that it is universally adherent. In other cases it is in a condition of incipient cystic degeneration. In many cases the cysts in the ovary are found to be in a state of suppuration, their contents having presumably become infected from the inflamed and suppurating Fallopian tubes. Primary ovaritis, either acute or chronic (apart from tuberculous disease), is a very rare condition.

The evidences of peritoneal inflammation are always most marked in the neighborhood of the fimbriated end of the tube, showing clearly that the pelvic peritonitis has originated by direct extension from the mouth of the inflamed tube or by the escape of morbid secretions therefrom.

The changes in the walls of the tube are as follows: in acute cases the mucous membrane is highly congested and swollen and covered with purulent or muco-purulent secretion; in chronic cases the condition varies according to whether the inflammatory secretions are pent up within the tube or have made their escape from the open fimbriated end. In the former case the mucous membrane is either distinctly ulcerated or covered with granulation tissue; in the latter, having got rid of its secretions, it is often found to have resumed more or less completely its normal appearance, except in the neighborhood of the adherent abdominal ostium, where it is frequently intensely congested and œdematous. The middle or muscular coat is greatly thickened and indurated from inflammatory exudation among the connective-tissue elements of the muscular layer.

In advanced cases the pus-containing tube becoming adherent to a cystic ovary, its wall may ulcerate and perforation occur, permitting the escape of the purulent contents of the tube into the interior of the cyst and the forming of tubo ovarian abscess. The result of such an accident is a sudden and most violent attack of pelvic peritonitis, placing the life of the patient in imminent peril. It must not, however, be supposed, whenever an inflamed and purulent tube is found suddenly to lead into a large abscess cavity, that the condition is necessarily one of tubo ovarian abscess. A tubo-ovarian abscess may be simulated by a sudden expansion of the tube itself, forming a curious and interesting variety of pyosalpinx.

Complications of Salpingitis.—When the salpingitis is unilateral, it is not at all unusual to find that the peritonitis spreading from the fimbriated end of the inflamed tube has passed over to the other side of the pelvis, involving the healthy uterine appendages of that side in a mass of adhesions. Under such circumstances closure of the abdominal ostium of the healthy tube is apt to occur, and to be followed by the development of a hydrosalpinx, which may, in its turn, itself become a source of suffering and ill health. Hæmatosalpinx, as a complication of salpingitis, is much more rare. In the great majority of cases hemorrhages within the tube and hæmatoceles of tubal origin are the consequence of tubal gestation, but now and then they occur as incidents in the course of the inflammatory processes just described. The pathological importance of the Fallopian tube is due to its peculiar anatomical position in the human subject. It is exposed to constant risk of infection, owing to the direct continuity of its lining membrane with that of the uterus and vagina, so that it is almost by a miracle if it escapes in any case of acute infective endometritis, whether septic or gonorrhœal. The uterine end of the Fallopian tube has a lumen only just large enough to admit a fine bristle. It will, therefore, be readily understood that it only requires a very slight amount of swelling of the mucous membrane, such as is probably inseparable from the mildest inflammatory attack, to block up that end completely. The position of matters, therefore, is that either there is no outlet at all for the morbid secretions, owing to the closure of one orifice by the swollen mucous membrane and the closure of the other by adhesions, or the only outlet is through the abdominal ostium into the peritoneal cavity. It is this fact of the absence of a safe outlet for inflammatory products that makes an attack of suppurative salpingitis so much more serious a matter than an equally severe attack of suppurative endometritis, and that invests the inflammatory affections of the Fallopian tube generally with such an exceptional and grave importance.

Referring to the advances that have been made in diagnosis, Dr. Cullingworth said that a little time ago the idea of being able to map out and examine the uterine appendages in the living subject would have been scouted with derision, but to-day he would be ashamed for any of his clinical clerks to be found, at the close of their three months' tenure of office, unable to diagnose, under reasonably favorable circumstances the size, position, consistence, and mobility of the Fallopian tubes, even if not of the ovaries as well, with a fair amount of accuracy.

The speaker then dwelt upon the improvement in treatment which had been made in recent times, and contrasted the operative and non-operative methods.

He gave the histories of three cases of purulent salpingitis that proved fatal owing to escape of the contents of the tube into the peritoneal cavity; in two instances through a rupture of the tube wall, and in the third through the still unclosed fimbriated extremity of the tube.

He then, by way of contrast, related three cases of very similar character to the foregoing, in which the diseased tubes were removed by operation. These cases terminated in perfect recovery. He believed that there could be no reasonable doubt that the lives of the first three of these six patients might have been saved by timely operation, or that the lives of the last three were so saved. But he did not wish to be misunderstood. He did not for a moment suggest that every case of inflamed Fallopian tubes should be operated upon. On the contrary, he believed that most of them recover without. But there is a large residuum of cases, most of them chronic, some few acute, in which nothing but an operation can save life. And there is a still larger number of cases where a timely operation rescues the patient from years of misery, incapacity, and chronic invalidism. The operation is, in short, not the one Heaven-sent remedy superseding all others, but an invaluable addition to our resources, which, when it is adopted in suitable cases, under a due sense of responsibility, and after full explanation to the patient and her friends both of the immediate risk and the ultimate physiological results, is capable of achieving triumphs as remarkable as any operation in surgery.

In the afternoon there was an excursion to Durham, and the University signalized the occasion by conferring the honorary degree of D.C.L. on Mr. Joseph White (ex-president), Dr. Withers Moore (a former president), Mr. Butlin (treasurer), Dr. Drummond, Dr. Cullingworth, Sir W. Foster, and the editor of the *Journal* (Mr. Ernest Hart).

In the evening there was a *conversazione* at the Newcastle Art Gallery, where a large number assembled.

Fifth Day, Saturday, August 5th.

This day was entirely devoted to excursions, and an ambulance review in the Park, but a large number of members had left and others were leaving. The exodus, in fact, began on Friday, but a sufficient number remained to carry out the programme of these lighter labors.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

BRITISH MEDICAL ASSOCIATION—TYPHOID AT A HEALTH RESORT—CONTAMINATED WATER—SURGERY OF THE AIR PASSAGES—MR. PITT'S LECTURES AT THE COLLEGE OF SURGEONS—TRACHEOTOMY AND INTUBATION—SCALDS OF THROAT—CONGENITAL DEFECTS OF LARYNX—DIPHTHERIA—A NEW METHOD OF REMOVING THE UTERUS.

LONDON, July 29, 1893.

NEXT week will be occupied with the annual meeting of the British Medical Association. This year we meet at Newcastle, and I shall forward you a full account of the proceedings. A number of reports have already been issued. This is a good plan, for it gives a day or two to digest them; but even so, there is usually no time for discussion, and the several reports are usually "rushed" through the general meetings, only a few determined spirits caring to give utterance to their discontent. The council thus manages to suppress criticism, and these reports go forth as expressing the views of the association, although everyone present is well aware that they are the uncriticized effusions of the officials. Of course, in the case of non-contentious subjects, this is of no great consequence; but in some of those instances where the managers are not representative of the members, the reports become *vox et prœteria nihil*.

A terrible epidemic of typhoid has occurred at Worthing, a pleasant seaside resort of some seventeen thousand inhabitants, situated on the south coast, a short trip from Brighton. In May and June there were three hundred and three cases notified, and it was hoped that the worst was over, but very soon a recrudescence occurred. There have been ninety-three deaths up to this date registered, and about one thousand attacks have been reported. It was thought at first that the outbreak was caused by the fouling of a new adit by the workmen employed, but it seems that while this actually occurred and perhaps commenced the epidemic, other contamination of the waterworks also took place either from a drain or from the admission of surface water. It is thought that the fall in the number of cases was probably due to the general boiling of the water by the terrified inhabitants, and that this precaution was neglected on the water being pronounced pure, and so the second outbreak was produced. It seems clear that the infection has remained an unusual length of time in the water-works or else has been renewed. It is, therefore, satisfactory to learn that the authorities have determined to obtain an entirely new supply, and in the meantime have arranged to use the water of West Worthing, where there has been no invasion.

Mr. Bernard Pitts took the surgery of the air passages and thorax in children for the subject of his lectures at the Royal College of Surgeons, confining himself almost entirely to conditions that had come under his notice at St. Thomas's Hospital and the Children's Hospital. Naturally tracheotomy and intubation loomed largely in this connection, as injuries and diseases of the larynx occupy so important a position among children. Scalds of the throat, *e.g.*, are still too common among children of the poorer classes. Of seventy-eight such cases admitted to St. Thomas's, sixty-seven were caused by the attempt to drink from the spout of a boiling kettle, the average age of the sufferers being a little over three. Mr. Pitts thinks intubation will take the place of tracheotomy in œdema from scalds when the injury is chiefly confined to the glottis and the surgeon is skilful in the use of the tubes. Congenital defects of the larynx and webs need not be interfered with unless there is difficulty of breathing. For papillomata, intubation was discountenanced and tracheotomy advised, followed in some cases by thyrotomy.

There is no doubt that tracheotomy has been more successful of late years than formerly. This is due to earlier operation and great attention to detail: delaying interference until the last moment, as formerly too often done, adds greatly to the risks. The high operation is almost always preferred in England for œdema, papillomata, foreign bodies impacted in the larynx, or inflammation of that organ; the low operation being employed when a foreign body has entered the trachea or a bronchus, as well as for syphilitic and, perhaps, tuberculous disease of the larynx. Some useful hints were given by the lecturer as to the operation itself, and, having watched many house surgeons in their earlier operations, he considered the chief dangers to be, too small an opening into the trachea and too great hurry to introduce the tube. After the trachea is opened, if dilating forceps or retractors are used, blood may be allowed to escape by coughing, or other contents can be removed and the tube introduced with as much deliberation as gentleness. Durham's tube is used at St. Thomas's, and ulceration, formerly so common, has rarely occurred since its adoption. Parker's tube is less expensive, simpler, and in use at the Children's Hospital. Rubber tubes are substituted a few days afterward if the secretions are normal, and in diphtheria when membrane ceases to form. Statistics of results in diphtheria are apt to be misleading, as epidemics differ so much in severity; it is most important to support the patient, and nasal feeding is better than nutrient enemata. The steam treatment is often overdone; the bed should not be near the fire with steam from the kettle playing over the face and body. A warm moist sponge should be kept over the tube, and the inner tube changed every hour or oftener while the discharges are thick. A zealous nurse may do harm by the frequent use of the feather. If obstruction occur, the surgeon should change the tube. A hand-spray of mercury perchloride, 1 in 1,000, was recommended for fauces, nasal passages, and the wound; but care must be exercised, and the spray must not enter the tube.

With regard to intubation, the lack of confidence still entertained in England was reflected by Mr. Pitts, who acknowledged that his own feelings were in favor of tracheotomy as a routine operation, though he admitted equally good results may be obtained from intubation; the chief factors in determining the choice being the nature of the case, the age of the patient, the experience of the operators, and the consent of friends. The lecturer gave the statistics of the two hospitals with which he is connected, and referred to recent results and opinions of both American and Continental surgeons. Moreover, he put in a statement by Dr. Collier, who has had charge of most of the cases at the Children's Hospital. Dr. Collier prefers intubation in all cases of laryngeal diphtheria when there is no supra-laryngeal obstruction and no evidence of membrane in the trachea. In this last event easy inspiration may result for a time, but the membrane acts as a valve to obstruct expiration, and insufflation of the lung will occur with great rapidity. When the diphtheria is also supra-laryngeal, the air passing over the membrane may set up bronchitis or produce broncho-pneumonia of the type of "cut-throat lung." In such cases, too, the local treatment of the nose and pharynx gives rise to choking, and the feeding of such cases is attended with the greatest difficulty.

A new method of removing the uterus has been brought before the Gynæcological Society by the president, Mr. Bowreman Jessett. He recently had the opportunity of performing his operation. He made peritoneal flaps, fore and aft, after securing the vessels and freeing the cervix with the scissors, in the same way as for a supra-vaginal amputation of the cervix, while an assistant pushed up the uterus, first with a speculum and then with a finger in the vagina. Instead of suturing the peritoneum, six ligatures were placed as follows: From the vaginal to the serous surface of the anterior flap; over the edges of both flaps; from the serous to the vaginal surface of the posterior flap. The ligatures were not tied, but simply drawn down into the vagina and pulled tight so as to close the peritoneal floor. The vagina was packed with iodoform gauze through the speculum. In reply to questions, Mr. Jessett said enucleation could not have been done in the case, the tumor being intra-mural; there was no difficulty in secur-

ing the uterine arteries, which could be felt in the flaps; it was not necessary to work deep down in the pelvis, as the parts could be brought up with a hook and the whole field of operation was well in view. By this method if any hemorrhage occurred it would be into the vagina, and so easily dealt with.

DRAFT OF A PROPOSED BILL TO ESTABLISH A BUREAU OF PUBLIC HEALTH.

The New York Academy of Medicine,
No. 19 West Forty-third Street, August 14, 1893.

In a previous paper the undersigned, a sub-committee of the National Quarantine Committee of the New York Academy of Medicine, submitted the first sections of a bill creating a Public Health organization in the General Government. Our purpose was to harmonize conflicting views on the plan of organization, about which there is a diversity of opinions, in order to concentrate upon a single measure the efforts of all who are interested in securing the necessary legislation. We herewith tentatively submit the complete bill organizing a Bureau of Public Health, for the purpose of eliciting a full and free discussion of the subject before finally determining the precise form which the committee will adopt. While the committee believe that the plan submitted is more nearly in accordance with the opinions of those whose judgment and experience are most valuable, it is prepared to give due consideration to any modifications which may be proposed. In preparing the details of the Bill the committee has reviewed all of the bills which have been before Congress during the past years, and have incorporated those provisions which seemed most important, the law of last year being most freely drawn upon.

All communications addressed to the Secretary of the Committee, Dr. J. H. Girdner, 31 West Thirty-eighth Street, will be duly considered.

Joseph D. Bryant, *Chairman.*
Richard H. Derby.
Edward G. Janeway.
T. Gaillard Thomas.
David Webster.
Stephen Smith.
J. H. Girdner, *Secretary.*

A Bill to establish within the Treasury Department a Bureau of Public Health.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled:

Creating Sanitary Districts.

Section 1. That for the purposes of this Act the States and Territories of the United States be, and are hereby, grouped into districts, to be known as "The Sanitary Districts of the United States," as follows:

The Northern Sanitary District shall include the States of Illinois, Indiana, Iowa, Michigan, Minnesota, Ohio, Wisconsin.

The Northeastern Sanitary District shall include the States of Connecticut, Massachusetts, Maine, New Hampshire, New York, Rhode Island, Vermont.

The Northwestern Sanitary District shall include the States of Idaho, Montana, North Dakota, Oregon, Washington, and the Territory of Alaska.

The Eastern Sanitary District shall include the States of Delaware, Maryland, New Jersey, Pennsylvania, Virginia, West Virginia, and the District of Columbia.

The Western Sanitary District shall include the States of California, Nevada, Utah, and the Territory of Arizona.

The Southern Sanitary District shall include the States of Arkansas, Alabama, Kentucky, Louisiana, Missouri, Mississippi, Tennessee.

The Southeastern Sanitary District shall include the States of Florida, Georgia, North Carolina, South Carolina.

The Southwestern Sanitary District shall include the State of Texas and the Territories of Indian Territory, New Mexico, Oklahoma.

The Central Sanitary District shall include the States of Colorado, Kansas, Nebraska, South Dakota, Wyoming. [*Original.*]

Organization of a Bureau of Public Health.

Sec. 2. That there shall be established in the Treasury Department, under the direction and supervision of the Secretary thereof, a Bureau of Public Health, to consist of a Commission of fifteen, of whom eleven shall be appointed by the President, by and with the advice and consent of the Senate, as follows, viz.: One Medical Commissioner from each of the "Sanitary Districts of the United States," provided in section one of this Act, and two commissioners at large; the compensation of the appointed commissioners, when actually engaged in the performance of their duties under this Act, shall be ten dollars per diem and reasonable expenses. The other four members of the Commission shall be the Surgeon-General of the Army, the Surgeon-General of the Navy, the Supervising Surgeon-General of the Marine Hospital Service, and an officer, learned in the law, detailed by the Attorney-General from the Department of Justice; these four members shall receive no compensation. [*Original.*]

Officers of the Commission.

Sec. 3. That the members of the Commission shall meet at such time and place as may be designated by the Secretary of the Treasury, and organize by the election, from their own number, of a President who shall be one of the members at large, and who shall receive five dollars per diem, in addition to the ten dollars per diem provided in the last section, when actually engaged in the performance of his duties under this Act. The Commission may appoint a Secretary not one of its number, and fix his salary at a sum not exceeding three thousand dollars annually. The Commission shall thereafter meet annually, at Washington, on the first Tuesday of October, and at such other times and places as the President of the Commission, with the approval of the Secretary of the Treasury, may designate. [*Original.*]

Sec. 4. That there shall be an Executive Committee of the Commission, consisting of its President, the Surgeon-General of the Army, the Surgeon-General of the Navy, and the Supervising Surgeon-General of the Marine Hospital Service, and the officer detailed by the Attorney-General. The Commission shall from time to time prescribe the duties of the Executive Committee, and may make all needful rules and regulations for its own control and for the guidance and discipline of all its officers and employees, and shall establish all rules and regulations for the government of national sanitation in all of its foreign and interstate relations, and special departments in the enforcement of the provisions of this Act. [*Original.*]

Conference with the State Board of Health.

Sec. 5. That when, in the opinion of the President of the Commission, the interest of the public health would be promoted by a conference of the Commission with the State Boards of Health of the several States, or of any sanitary district or districts, he is hereby authorized to invite, with the approval of the Secretary of the Treasury, said State Boards of Health, or such number thereof as he may designate, each to delegate one of its members to meet the Commission in conference at such time and place as he may appoint; the President of the Commission shall be the President, and the Secretary of the Commission shall be the Secretary of any such conference; the delegate in attendance upon the conference from each State Board of Health shall be entitled to receive reasonable compensation for expenses for a session not exceeding three days, to be paid on vouchers provided by the Secretary of the Treasury. [*Original.*]

Sec. 6. That the duties of the Bureau of Public Health shall be to collect and diffuse information upon all matters

affecting the public health; to advise the several departments of the Government, the Executives of the several States, and all Health authorities on all questions submitted to it, or whenever in the opinion of the Bureau such advice may tend to the preservation and improvement of the public health; to secure the best sanitary condition of vessels from foreign ports; to prevent the introduction of contagious and infectious diseases into the United States, and their spread from one State into another; to co-operate with and aid State and municipal health authorities in the execution and enforcement of rules and regulations to suppress contagious and infectious diseases; and, in general, to be the medium through which the General Government shall adopt such measures and take such action as will most effectually protect and promote the health of the people of the United States. [*Selected from several bills.*]

Collection and Diffusion of Information.

Sec. 7. That the Bureau of Public Health may, with the approval of the Secretary of the Interior, make investigations, both in the United States and, if necessary, in foreign countries, into the nature, origin, and prevention of contagious, epidemic, and other diseases, as well as the causes and conditions of particular outbreaks of disease in the United States, and may publish and distribute documents relating to the prevention of disease. [*Section* 4, *Senate Bill* 1334, 1886.]

Sec. 8. That to enable the Bureau of Public Health to acquire and have in its possession for distribution information on all subjects affecting the public health which require accurate and reliable scientific investigations, the Commission is hereby authorized, with the approval of the Secretary of the Treasury, to engage the services of experts in such laboratories in the United States as are best adapted by location, equipment, or special fitness to prosecute and complete the investigation required. [*Original.*]

Sec. 9. That as soon as practicable after this act shall take effect the Commissioners appointed from the Sanitary Districts shall each in his respective District examine all of the means and measures employed by State, municipal, and other health authorities to prevent the introduction of contagious and infectious diseases into the United States, and their spread from one State or Territory into another, and report the fact to the Bureau of Public Health, and the Commission shall embody these facts in a report to the Secretary of the Treasury, who shall transmit the same to Congress with such recommendations as he may deem important. Thereafter each Commissioner shall annually report upon the measures employed, with the result, in his Sanitary District to prevent the introduction, origin, and spread of contagious and infectious diseases, and the Commission shall embody the facts in its annual report to the Secretary of the Treasury. [*Original.*]

Sec. 10. That it shall also be the duty of the Bureau of Public Health to obtain information of the sanitary condition of foreign ports and places from which contagious and infectious diseases are or may be imported into the United States, and to this end the consular officers of the United States at such ports and places as shall be designated by the Bureau of Public Health, shall make to said Bureau weekly reports of the sanitary condition of the ports and places at which they are respectively stationed, according to such forms as said Bureau may prescribe; and the Bureau of Public Health shall also obtain, through all sources accessible, including State and municipal sanitary authorities throughout the United States, weekly reports of the sanitary condition of ports and places within the United States; and shall also, as far as it may be able, by means of the voluntary co-operation of State and municipal authorities, of public associations, and private persons, procure information relating to the climatic and other conditions affecting the public health, and the existence of epidemic, endemic, and other diseases; statistics relating to marriages, births, and deaths.

Sec. 11. That the Commission shall prepare, publish, and transmit to the medical officers of the Army, Navy, and the Marine Hospital Service, to collectors of customs, and to State and municipal health officers and authorities, weekly abstracts of the consular sanitary reports and other pertinent information received by the Bureau of Public Health. [*Section*]

Advising Departments of Government.

Sec. 12. That whenever any department of Government, or the Executive of any State or Territory, or the authorities of the District of Columbia, or the health authorities of any State or municipality, shall request information from the Bureau of Public Health in regard to any matter pertaining to the protection or promotion of the public health, said Bureau shall promptly furnish such information as it may have on record, together with any necessary or pertinent advice; and whenever information shall be received by the Bureau which the interests of the public health require should be promptly communicated to any department of the Government, or to any State or municipal officer, such information shall be forthwith furnished to the respective department or officer. [*Original.*]

Notification of Epidemic Diseases.

Sec. 13. That the Commission shall take such action by correspondence or conference as will tend most effectually to secure the co-operation of State, municipal, and local boards of health in establishing and maintaining an efficient and accurate system of notification of the existence and progress of contagious and infectious diseases in the United States, and said Commission shall also by co-operation with the proper health authorities of foreign nationalities and municipalities endeavor to extend to the United States a reliable system of international notification of the existence and progress of such diseases as cholera, yellow fever, typhus fever, and small-pox. [*Original.*]

Securing the Best Sanitary Condition of Vessels.

Sec. 14. That the Bureau of Public Health shall make such rules and regulations, with the approval of the Secretary of the Treasury, as are necessary to be observed by vessels at the port of departure and on the voyage, where such vessels sail from any foreign port or place, to secure the best sanitary condition of such vessel, her cargo, passengers, and crew, which shall be published and communicated to and enforced by the consular officers of the United States. None of the penalties herein imposed shall attach to any vessel, or owner or officer thereof, until a copy of this act, with the rules and regulations made in pursuance thereof, has been posted up in the office of the consul or other consular officer of the United States for ten days, in the port from which said vessel sailed; and the certificate of such consul or consular officer over his official signature shall be competent evidence of such posting in any court of the United States. [*Latter portion of Section* 3, *law of* 1893.]

Sec. 15. That the Bureau of Public Health shall, with the approval of the Secretary of the Treasury, from time to time issue to the consular officers of the United States, and to the medical officers serving at any foreign port, and otherwise make publicly known, the rules and regulations made by it, and approved by the Secretary of the Treasury, to be used and complied with by vessels in foreign ports for securing the best sanitary condition of such vessels, their cargoes, passengers, and crew, before their departure for any port in the United States, and in the course of the voyage, and all such other rules and regulations as shall be observed in the inspection of the same on the arrival thereof at any quarantine station at the port of destination, and for the disinfection and isolation of the same, and the treatment of cargo and persons on board, so as to prevent the introduction of cholera, yellow fever, or other contagious or infectious diseases. [*First portion of Section* 5, *law of* 1893.]

Preventing the Introduction of Contagious and Infectious Diseases.

Sec. 16. That it shall be unlawful for any merchant-ship or other vessel from any foreign port or place to enter any port of the United States except in accordance with the provisions of this act, and with such rules and regulations of State and municipal health authorities as may be made in pursuance of, or consistent with, this act; and any such vessel which shall enter, or attempt to enter, a port of the United States in violation thereof shall forfeit to the United States a sum, to be awarded in the discretion of the court, not exceeding $5,000, which shall be a lien upon said vessel, to be recovered by pro ceedings in the proper district court of the United States. In all such proceedings the United States district attorney for such district shall appear on behalf of the United States; and all such proceedings shall be conducted in accordance with the rules and laws governing cases of seizure of vessels for violation of the revenue laws of the United States. [*Section* 1, *law of* 1893.]

Sec. 17. That any vessel at any foreign port clearing for any port or place in the United States shall be required to obtain from the consul, vice-consul, or other consular officer of the United States at the port of departure, or from the medical officer where such officer has been detailed by the President for that purpose, a bill of health, in duplicate, in the form prescribed by the Secretary of the Treasury, setting forth the sanitary history and condition of said vessel, and that it has in all respects complied with the rules and regulations in such cases prescribed for securing the best sanitary condition of the said vessel, its cargo, passengers, and crew; and said consular or medical officer is required, before granting such duplicate bill of health, to be satisfied that the matters and things stated therein are true; and for his services in that behalf he shall be entitled to demand and receive such fees as shall by lawful regulation be allowed, to be accounted for as is required in other cases.

The President, in his discretion, is authorized to detail any medical officer of the Government to serve in the office of the consul at any foreign port for the purpose of furnishing information and making the inspection and giving the bills of health hereinbefore mentioned. Any vessel clearing and sailing from any such port without such bill of health, and entering any port of the United States, shall forfeit to the United States not more than $5,000, the amount to be determined by the court, which shall be a lien on the same, to be recovered by proceedings in the proper district court of the United States. In all such proceedings the United States district attorney for such district shall appear on behalf of the United States; and all such proceedings shall be conducted in accordance with the rules and laws governing cases of seizure of vessels for violation of the revenue laws of the United States. [*Section* 2 *of law of* 1893.]

Sec. 18. That it shall not be lawful for any vessel to enter any port of the United States to discharge its cargo, or land its passengers, except upon a certificate of the health officer at such quarantine station certifying that said rules and regulations have in all respects been observed and complied with, as well on his part as on the part of the said vessel and its master, in respect to the same and to its cargo, passengers, and crew; and the master of every such vessel shall produce and deliver to the collector of customs at said port of entry, together with the other papers of the vessel, the said bills of health required to be obtained at the port of departure, and the certificate herein required to be obtained from the health officer at the port of entry; and that the bills of health herein prescribed shall be considered as part of the ship's papers, and when duly certified to by the proper consular or other officer of the United States, over his official signature and seal, shall be accepted as evidence of the statements therein contained in any court of the United States. [*Latter part of section* 5, *law of* 1893.]

Sec. 19. That the Commission, with the approval of the Secretary of the Treasury, shall have authority to forbid entry of vessels from ports known or suspected to be infected with cholera, yellow fever, small-pox, or other declared quarantinable disease into all minor approaches to a port of entry or into any inlet or place within the jurisdiction of the United States not provided with a complete quarantine plant, in order to compel such vessels to be subjected to maritime sanitation at the quarantine station equipped for that purpose and commanding the scope of region in question. [*Sec.* 15, *House Bill* 9757, 1893.]

Sec. 20. That on the arrival of an infected vessel at any port not provided with proper facilities for treatment of the same, the Commission may remand said vessel, at its own expense, to the nearest national or other quarantine station where accommodations and appliances are provided for the necessary disinfection and treatment of the vessel, passengers, and cargo; and after treatment of any infected vessel at a national quarantine station, and after certificate shall have been given by the United States quarantine officer at said station that the vessel, cargo, and passengers are each and all free from infectious disease, or danger of conveying the same, said vessel shall be admitted to entry to any port of the United States named within the certificate. But at any ports where sufficient quarantine provision has been made by State or local authorities, the Commission may direct vessels bound for said ports to undergo quarantine at said State or local station. [*Sec.* 6, *law* 1893, *modified.*]

Preventing the Spread of Cholera and Yellow Fever from One State into Another.

Sec. 21. That whenever it shall be made to appear to the Commission that cholera or yellow fever exists in any State or Territory and that there is danger of the spread of such disease by the usual channels of transportation to other States and Territories, the Commission is authorized to adopt such rules and regulations with the approval of the Secretary of the Treasury, as, in its judgment, may be necessary in order to prevent the spread thereof from one State or Territory to another, and to employ such inspectors and other persons as may be necessary for the purpose aforesaid, and any person who shall knowingly disobey or violate any order, rule, or regulation made pursuant to the authority herein conferred shall be deemed guilty of a misdemeanor, punishable by a fine of not less than five hundred dollars and by imprisonment for a period of not less than one year. [*Senate Bill* 3467, 1888.]

Sec. 22. That rules and regulations framed and approved as herein authorized shall be promulgated, so that when cholera or yellow fever shall be ascertained by the Bureau to exist in any port or place within any one of the United States or Territories, or the District of Columbia, in such form as threatens its spread, as to prevent, as far as practicable, the communication of the same to other ports and places within other States by means of vessels and vehicles engaged in the transportation of goods or passengers between two or more States, or States and Territories, and the District of Columbia, whether by land or water; in that case, the Commission may select suitable localities for establishing stations on rivers and other lines of inter-State commerce and travel by railroads, and may cause to be erected necessary temporary buildings for the disinfection of passengers, baggage, cargoes, vessels, and vehicles, and may enforce such rules and regulations relating thereto as may have been prescribed therefor. It shall be the duty of the Bureau, so far as it lawfully may, in the execution of the powers conferred upon it by law, to correspond and co-operate with similar local officers, boards, and authorities acting under laws of the States, or Territories, or the District of Columbia, in sanitary measures, to prevent the introduction and spread of contagious and infectious diseases from foreign countries into the United States, and from one State or Territory into any other State or Territory by

means of commercial intercourse, or upon and along the lines of inter-State trade and travel; and to that end it shall be lawful for the Commission to confer upon any such local officer or board within or near the locality where his or its authority is exercised, power also to enforce the provisions of this act and any rules and regulations made in pursuance thereof. [*Sec.* 5, *of Senate Bill* 108. 1879, *modified.*]

Aid of State and Municipal Health Authorities.

Sec. 23. That the Commission shall, under the direction of the Secretary of the Treasury, co-operate with and aid State and municipal health authorities in the execution and enforcement of the rules and regulations of such authorities, and in the execution and enforcement of the rules and regulations made by the Commission and approved by the Secretary of the Treasury to prevent the introduction of contagious or infectious diseases into the United States from foreign countries, and into one State or Territory or the District of Columbia from another State or Territory or the District of Columbia; and all rules and regulations made by the Commission and approved by the Secretary of the Treasury shall operate uniformly and in no manner discriminate against any port or place; and at such ports and places within the United States as have no quarantine regulations under State or municipal authority, where such regulations are, in the opinion of the Commission, necessary to prevent the introduction of contagious or infectious diseases into the United States from foreign countries, or into one State or Territory or the District of Columbia from another State or Territory or the District of Columbia, and at such ports and places within the United States where quarantine regulations exist under the authority of the State or municipality which, in the opinion of the Commission, are not sufficient to prevent the introduction of such diseases into the United States, or into one State or Territory or the District of Columbia from another State or Territory or the District of Columbia, the Commission shall, if in its judgment it is necessary and proper, make such additional rules and regulations as are necessary to prevent the introduction of such diseases into the United States from foreign countries, or into one State or Territory or the District of Columbia from another State or Territory or the District of Columbia, and when said rules and regulations have been made they shall be promulgated by the Commission and enforced by the sanitary authorities of the States and municipalities, where the State or municipal health authorities will undertake to execute and enforce them; but if the State or municipal authorities shall fail or refuse to enforce said rules and regulations, the President shall execute and enforce the same and adopt such measures as in his judgment shall be necessary to prevent the introduction or spread of such diseases, and may detail or appoint officers for that purpose. [*Sec.* 3, *law* 1893, *modified.*]

Employment of Experts.

Sec. 24. That the President is authorized, when requested by the Bureau of Public Health, and when the same can be done without prejudice to the public service, to detail officers from the several Departments of the Government for temporary duty, to act under the direction of said Bureau, to carry out the provisions of this act; and such officers shall receive no additional compensation except for actual and necessary expenses incurred in the performance of such duties. When a detail of suitable officers cannot be made, the Commission may, with the approval of the Secretary of the Treasury, employ such experts and for such time and in such manner as the exigencies of the Service may require. [*Sec.* 5, *House Bill* 1526, 1893.]

Sec. 25. That whenever the proper authorities of a State shall surrender to the United States the use of the buildings and disinfecting apparatus at a State quarantine station, the Commission shall cause an examination thereof to be made by its own members, or by a competent person, or persons, and if the said station, buildings, and disinfecting apparatus be found adapted to the purposes of a quarantine, and the Commission approve of their use as such, the Secretary of the Treasury shall be authorized to receive them, and to pay a reasonable compensation to the State for their use. [*Sec.* 8, *law of* 1893, *modified.*]

Execution of the Orders, Rules, and Regulations of the Bureau of Public Health.

Sec. 26. That all orders, rules, and regulations of the Bureau of Public Health relating to Sanitation in any branch of the public Service, or to prevent the introduction of contagious and infectious diseases into the United States, and their spread from one State or Territory into another State or Territory, or the District of Columbia, through, or by means of any branch of the Public Service, the medical officers of such Service shall execute such orders, rules, and regulations, and to this end the Surgeon-General of the Army shall perform all such duties in respect to the Army, the Surgeon-General of the Navy shall perform all such duties in respect to the Navy, and the Surgeon-General of the Marine Hospital Service shall perform all such duties in respect to quarantine and quarantine regulations which are provided by this act.

Extraordinary Power given to the President.

Sec. 27. That whenever the Commission shall certify to the President, and it shall appear to his satisfaction that, by reason of the existence of cholera or other infectious or contagious diseases in a foreign country, there is serious danger of the introduction of the same into the United States, and that notwithstanding the quarantine defence this danger is so increased by the introduction of persons or property from such country that a suspension of the right to introduce the same is demanded in the interest of the public health, the President shall have power to prohibit, in whole or in part, the introduction of persons and property from such countries or places as he shall designate, and for such period of time as he may deem necessary. [*Sec.* 7, *law* 1893, *modified.*]

Special Appropriation.

Sec. 28. That there shall be, and hereby is, appropriated, out of any moneys in the Treasury not otherwise appropriated, the sum of one million dollars, to be expended, or so much of the same as may be necessary from time to time, under the direction of the President and according to his discretion, to meet emergencies arising in the execution of the provisions of this act. [*Sec.* 8, *laws*, 1893.]

Report, Printing, etc.

Sec. 29. That the Bureau of Public Health shall make an annual report of its operations to the Secretary of the Treasury, who shall transmit the same to Congress, with such recommendations as he may deem important to the public interests; and said report, if ordered to be printed by Congress, shall be done under the direction of the Board; and that all mail matter of whatever class relative to the Bureau of Public Health and its duties, and addressed to its secretary and indorsed "Official business, Bureau of Public Health," shall be transported free of postage; and if any person shall make use of any such indorsement to avoid the payment of postage on his private letter, package, or other matter in the mail, the person so offending shall be guilty of a misdemeanor, and be subject to a fine of five hundred dollars, to be prosecuted in any Court of competent jurisdiction. [*Senate Bill* 643, 1885.]

The New York State Medical Examinations.—A gentleman, an American, who has been educated in Germany, and who recently returned and underwent the examination for license to practise in this State, says that the examination passed by him was of the same character and extent as that which would be required in Germany. Why should it not be so?

PREVENTION OF BLINDNESS FROM OPHTHALMIA NEONATORUM THROUGH TREATMENT AND LEGISLATION.[1]

BY A. E. PRINCE, M.D.,

SPRINGFIELD, ILL.

MR. PRESIDENT AND GENTLEMEN: Interest in the prevention of blindness due to ophthalmia neonatorum having increased during the past twenty-five years, the author believes that a concerted effort on the part of the profession should be made to diminish its frequency; and to this end he has endeavored to summarize such facts as may serve to bring the subject before the Society, in the hope that good may be ultimately accomplished.

The importance of the subject is in direct proportion to the frequency with which blindness results from the operation of this cause, and those who have given the subject no consideration are invariably surprised on learning the magnitude of its operation.

My attention was first drawn in this direction by the results of an examination of the children in the Illinois State Institution for the Education of the Blind. In this institution there were two hundred and seven pupils. As near as possible, it was ascertained, as shown by the following table, that one hundred and sixteen, or 62.9 per cent., of these children lost their sight from communicable disease which could have been prevented had the requisite precautions been observed.

CAUSES.

Ophthalmia neonatorum (contagious)	44	
" purulent (contagious)	38	
" Trachomatous (contagious)	34	116
Congenital		25
Measles		3
Meningitis		5
Sympathetic inflammation		2
Scarlet fever (non-contagious)		4
Scrofula		9
Small-pox		18
Traumatism		18
Unknown		22
Total		222

Leaving out of account the unknown twenty-two, the above tabulation of two hundred cases, in which the cause could be ascertained, indicates the percentage of blindness due to each cause.

As indicated by the table, forty-four, or twenty-four per cent., of the total number lost their eyes from ophthalmia neonatorum. Somewhat surprised at the result, I was led to look up the observations of others, and found that this was not above the average.

Magnus has shown, in his extensive work, "Die Blindheit: ihre Entstehung und ihre Verhütung," that of children under sixteen years of age 38.78 per cent. became blind from ophthalmia neonatorum.

Fuchs found in an examination of 3,204 cases of blindness, in various parts of Europe, that 23.5 per cent. were due to ophthalmia of the new-born. An average of all the asylums of Germany gave 25.83 per cent. Similarly the returns of Austria and Hungary showed an average of 20.4 per cent. The New York State Institution for the Blind at Batavia, having 128 inmates, showed 23.4 per cent. blind from this cause.

[1] Read at the meeting of the Illinois State Medical Society, May 16, 1893.

Entire communities have been examined to determine the relative influence of the various causes of the production of blindness. In Brunswick twenty-eight per cent. and in Nassau thirteen per cent. were found to have lost their sight from ophthalmia neonatorum.

Fuchs estimates that at least ten per cent. of the blind of all ages, and in all the countries of Europe, are due to the operation of this one cause, making in Europe alone thirty thousand blind from ophthalmia neonatorum.

Being impressed with the magnitude of the influence of this cause, three questions become of interest: 1st. What are the results of prophylactic measures? 2d. What are the results of intelligent treatment? 3d. What has been and should be done by legislation?

Prophylaxis.—1st. The earliest available record of an effort to prevent ophthalmia neonatorum is that of Gibson in 1808. That he understood the indications is shown by his original propositions, which were made three-quarters of a century ago, and before the birth of our knowledge regarding antisepsis, and before the discovery of carbolic and salicylic acids. They are prophetic, concise, and complete, and constitute the generalization of modern facts.

First. Control the vaginal discharges as early as possible during pregnancy. Second. At the time of delivery remove the injurious secretions from the vagina. Third. Immediately after delivery clean the eyes of the infant with a fluid which shall remove the injurious material or destroy its action.

The next step was that of Bischoff, who suggested in 1875 the disinfection of the vagina by means of carbolic acid, and the eyes by means of salicylic acid. In 1876 Schiess proposed that midwives should disinfect the eyes immediately after birth.

At this time the importance of preliminary disinfection of the vagina became generally recognized and put in practice in all well-organized lying in hospitals. Still it was found impossible by this means alone to prevent the danger of infection. Though thoroughly removed, secretions will re-form during a protracted delivery; and notwithstanding this precaution, no small percentage of infection continued to exist.

In the opinion of Fuchs, infection does not always or even usually occur during the delivery, but afterward, when the child opens the eyes and admits the material which adheres to the lids and lashes; the admission of which is still further encouraged by winking: hence the importance of directing prophylactic efforts more particularly to the eyes.

The first demonstration regarding prophylaxis was made by Perringer. He observed that if undertaken within three minutes subsequent to the admission of pus, infection was prevented by the careful irrigation of the cul-de-sac with warm water and the subsequent application of cold compresses. These observations were verified by Abegg.

Schirmer, thinking the bath water was the greatest source of infection by being the medium of transferring the secretion from the body to the eyes, used a dry napkin to clean the face and interdicted the application of water to the face until after the second day.

Fieuzal advocated the irrigation of the eye with a four-tenths per cent. solution of carbolic acid and the subsequent application of cold compresses. Borax, salicylic acid, and chlorine water were in turn advocated and condemned.

After pursuing and abandoning in turn each of the

above suggestions, Credé secured immortal fame by his great discovery regarding the action of silver nitrate as a germicide of the highest order in this class of cases.

At first his method consisted of careful washing with a solution of borax, the application of a two per cent. solution of silver nitrate, and following this for twenty-four hours with compresses moistened with a solution of salicylic acid. By degrees this treatment was curtailed by the discontinuance of the preliminary use of borax and the subsequent compresses, leaving the silver portion of the treatment, which alone is known by his name.

Immediately after the delivery the eyes are carefully washed with plain water, and a single drop of a two per cent. solution of argentum nitrate is let fall from a pipette on to the cornea, over which the lids are immediately closed. No especial reaction is observed to follow, and after two days the redness has vanished. He found that in place of having a 10.8 per cent of ophthalmia neonatorum, as was the case previous to the adoption of antiseptic precautions, the development of the disease was reduced to one- or two-tenths of one per cent.

In one series of sixteen hundred births among a class of individuals in which gonorrhœa was always to be suspected, inflammation was observed to occur in but one or two cases. Reports of the brilliant results following this method of prophylaxis led to its being subjected to the test of experience and observation by the leading obstetricians of Europe.

The following table, compiled by Fuchs,[1] illustrates the results following the execution of the method as compared with the experience of the same observers before its adoption.

Comparison of Results of Various Methods of Prophylaxis in Ophthalmia Neonatorum.

Author.	Previous to Prophylaxis. Total number of births.	Cases of blennorrhœa.	Per cent.	After Inauguration of Prophylaxis. Prophylactic methods.	Total number of births.	Cases of blennorrhœa.	Per cent.

No stronger proof of the efficiency of the method would seem to be required. It has been endorsed by the leading obstetricians and oculists of Europe and America, and is now in use in most of the lying-in hospitals of the world. Yet the objection will be raised here that, though it is undoubtedly correct and should be practised in hospitals where women of doubtful character are the rule, it is too heroic for private practice when one knows his patient to be free from gonorrhœal infection.

This question is one of vital importance, and deserves discussion. It has been my lot in the past few years to see eyes lost from ophthalmia neonatorum in which the mothers were wives of clergymen, merchants, and farmers who have never been suspected, but in whose cases the development of purulent ophthalmia in the eyes of the infant is the best evidence of the existence of at least a malignant leucorrhœa. It is well known that gleet, which in the male would be a source of perpetual or periodic discomfort, owing to the loose folds of the vagina is often never suspected by the incumbent, much less her physician. On this account it is never certain where the line shall be drawn, and when it is safe to omit the remedy. Besides the remedy is absolutely safe and harmless in any case. At most, a slight swelling and redness is observed, which disappears in forty-eight hours, and should not stand as against the danger of infection.

Prevalence of gonorrhœa is in proportion to the density of population, and hence the frequency of ophthalmia neonatorum is greater in Europe than in America—is greater in large cities than in country towns; but even in small towns the comparative infrequency of the disease makes it relatively more treacherous and dangerous; for a danger which is kept permanently before the mind will assert itself and provoke popular demand for means by which it shall be removed; while one which is rarely observed is easily forgotten, and we are only alarmed by its presence after it has stricken its victim.

In Sangamon County, to my knowledge, within a period of six months, the blindness of two children from ophthalmia neonatorum would have been prevented had the Credé method been in general use. In each case the father had contracted gonorrhœa, while the mother was ignorant of its existence. Would not the prevention of blindness in these two compensate for a slight additional attention in the case of many? The answer to this will depend somewhat on the position taken regarding treatment.

Second. What are the facts regarding treatment?

Dr. Pendergast, health officer of Cincinnati, tells us that one-third of the deliveries of that city are conducted by midwives, most of whom consider themselves competent to take charge of a simple inflammation of the eyes.

A large portion of the remainder are not seen by a physician more than once after the delivery, and the care of the child is left in the hands of the nurse, who is usually as conceited as the midwife. The following too often occurs: During the first and second days the eyes are kept closed. On the third or fourth day a slight amount of discharge, it may be with swelling, is observed. Nurse takes little account of it, applies chamomile tea or mother's milk, and hopes it will be better. Next day there may be more swelling or discharge. Baby has taken cold or seen too much light. More mother's milk or chamomile tea. Perhaps a poultice of slippery elm or rotten apples is applied. If worse on the following day, a physician is called. He may or may not secure a view of the cornea. In the absence of an available specialist he assumes charge, and does the best he knows. A solution of boric acid or other mild germicide is prescribed, and they are told to clean the eyes every half hour, and to let him hear on the following day. The nurse executes the directions, for she is now alarmed. The lids are not everted. The acrid discharge remains. The cornea is macerated and infected, and the chances are, twenty-five in one hundred, that sight will be permanently impaired.

[1] Die Ursachen und die Verhütung der Blindheit. p. 129.

My purpose, at this juncture, is to call attention to the fact that reports from a number of careful and conscientious observers go to show that one hundred per cent. of these cases should escape injury of the cornea, and recover with unimpaired vision, if each case were reported immediately to a physician, and each physician, with the courage of his convictions, put his information into practice without hesitation.

In order to emphasize the results of intelligent treatment, reference is directed to the observations of Dr. S. C. Ayres, of Cincinnati, who has published a comparison between two series of one hundred cases each.

The first series is that of one hundred consecutive cases taken from private practice. In each case is shown the age of the child when first seen; what complication, if any: and result in each eye. These cases were not neglected for want of means, but for the want of knowledge regarding the importance of early and correct treatment.

From a study of this series, the following has been adduced: Forty-two per cent. had corneal complication at the time of the first visit, leading to permanent impairment of sight. Fifty eight per cent. were free from corneal complication at the date of the first visit. Of these, in no case did the cornea become involved during treatment.

The second series was that of one hundred consecutive cases treated from the commencement in the Cincinnati Hospital. No case in this entire series developed corneal complication or suffered impairment of vision in a single eye. The reputation of Dr. Ayres for conservatism in observation and expression, together with the fact that one simple line of treatment has conducted one hundred consecutive cases to a successful issue, leads me to quote from him regarding the treatment which has been pursued in the Cincinnati Hospital during a period of fifteen years:

"The treatment of these cases, which was carried out almost entirely by the internes under the supervision of the attending oculist on duty, was, with little variation, as follows: The eyes were cleansed every hour or half hour or even oftener, in cases where the discharge was very profuse, by gently separating the eyelids with the fingers and removing the accumulated pus with cotton or a camel's hair brush. A solution of alum, gr. ij., ad aqua, ℥ ss., or of argent. nitr., gr. ij., ad aqua, ℥ j., was dropped into the eyes every hour or two. Cold compresses were used in some cases, and seemed to be very grateful. Every morning the eyelids were everted and brushed with a solution of argent. nitrat., grs. v., ad xx., ad aqua dest., ℥ j, according to the severity of the case, and the lids washed off with tepid water. Unless the swelling of the lids mechanically prevented it, the cornea was inspected daily in each case. As the case improved the interval between the instillations of alum and argent. nitrat. was continued in a weaker or stronger solution, until every trace of the disease had disappeared.

"The greatest stress was laid upon the thorough cleansing of the eye in the acute stages of the disease; and this was attended to not only by day, but by night. To this part of the treatment do we owe the immunity of the cornea from ulceration. The pus is neutralized or coagulated by the action of the nitrat. and alum, and its corroding effects thus prevented.

"Another important point in hospital treatment is that cases receive attention immediately the slightest swelling of the lids is noticed, and the severity of the disease is probably thus diminished."

Note.—Upon recent correspondence with Dr. Ayres, he writes: "At the present time I use a solution of sublimate more frequently; but doubt if it is better than alum. When a child is born in the Cincinnati Hospital its eyes are treated at once with a solution of nitrate of silver, and this prophylactic treatment has about stamped the disease out, so that it is seldom seen."

To further illustrate the amenability of the disease to treatment, at my suggestion Dr. H. W. Woodruff, house surgeon of the Illinois Charitable Eye and Ear Infirmary, searched the records of the infirmary for the year commencing April 1, 1892, and ending April 1, 1893. He found the total number of cases treated to be fifty-three. In four cases the cornea of both eyes had sloughed, resulting in blindness. In eight cases the cornea was ulcerated, recovering with impaired vision. Forty-one, admitted before corneal complication had occurred, recovered with unimpaired vision.

In this report it appears that twenty-two and a half per cent. of the cases suffered irretrievable injury before they were reported; while of the seventy seven and a half per cent. in which treatment was commenced before corneal complication occurred, none suffered impairment or loss of vision.

In these cases the local treatment was substantially that pursued in the Cincinnati Hospital, except that many were treated as out patients, and hence received less care and regular attention.

In the treatment of ophthalmia neonatorum, the silver nitrate has given better results than any other agent, and on account of merit has been accorded supremacy over all others. The results, as shown above, so far as efficiency is concerned, are such as leave little more to be desired. Besides, there is nothing in the treatment which cannot be carried out by any intelligent physician who will take a little pains to acquire the manipulations of the lids. When the swelling is great, they are everted by slight pressure on the lids with the first and second fingers; but as the swelling recedes, it often becomes necessary to exercise some traction on the cilia, when the eversion is accomplished with or without the aid of a pencil or similar object over which the lids may be turned. It may not be amiss to state that there is but one proper position for the patient in treating ophthalmia neonatorum, viz.: body recumbent in the lap of nurse or attendant; hands held, feet free, with head of child resting between the knees of the physician. In this position the efforts of the child do not move the head, and the touch of the operator may be both firm and gentle.

Legislation.—Third. Our third inquiry is relative to legislation, to take the management of these cases away from the irresponsible and ignorant, and intrust them to the intelligent guidance of a qualified physician.

The first legislation affecting the prevention of blindness by means of limiting the liberty of nurses and midwives occurred in Switzerland in 1865. Here it was made obligatory on the part of midwives and nurses to report every case of ophthalmia of the new-born immediately upon its discovery. Professor Horner became the champion of the legislative efforts, and devoted himself, through his personality and skill, toward increasing the efficiency of the law. During his lifetime he proudly enjoyed the knowledge of the fact that no child born since 1865 was admitted into the large Institution for the Blind in Zurich with sight lost from ophthalmia neonatorum.

In Prussia the regulations for 1878 give particular directions and instructions concerning this important point. In France, in 1888, the official directions for nurses and midwives urged the danger of delay. Austria, in 1882, established official directions for nurses, by which it now requires that every nurse or midwife, upon the development of ophthalmia of the new-born, should immediately call a physician.

The Hungarian secretary of the interior, this same year, issued a pamphlet upon the subject of the ophthalmia of infants, designed for distribution among the nurses of that country. In this country the first steps affecting legislation for the prevention of blindness were inaugurated by Dr. Lucian Howe, of Buffalo, N. Y. In 1887 he presented the matter to the American Ophthalmological Society, which was followed by an animated discussion, and the appointment of the committee to report on the "Causes and Prevention of Blindness," consisting of Lucian Howe, Swan Burnett, and Joseph A. Andrews. In 1889 Dr. Howe read a paper at the meeting

of the New York State Medical Society on "Purulent Conjunctivitis of Infancy," and closed with the recommendation that the committee on legislation formulate a law requiring nurses and midwives to report at once to some legally qualified practitioner. This was done, and at the next meeting of the Legislature the following law was passed:

"The people of the State of New York, represented in Senate and Assembly, do enact as follows:

"SECTION 1. Should any midwife or nurse having charge of an infant in this State, notice that one or both eyes of such infant are inflamed or reddened at any time within two weeks after its birth, it shall be the duty of such midwife or nurse so having charge of such infant to report the fact in writing, within six hours, to the health officer or some legally qualified practitioner of medicine of the city, town, or district in which the parents of the infant reside.

"SECTION 2. Any failure to comply with the provisions of this act shall be punished by a fine not to exceed one hundred dollars, or imprisonment not to exceed six months, or both.

"SECTION 3. This act shall take effect on the first of September, eighteen hundred and ninety."

Since that time a similar bill has passed the Legislature of Maine. Bills to effect the same purpose have been introduced this past winter in the Legislatures of Ohio, Pennsylvania, Minnesota, Illinois, and the Dominion of Canada.

The New York bill, with a slight modification, was introduced at my suggestion by Senator Higbee, in the Illinois Legislature. It has passed the senate and is pending in the house. Owing to the unusual length of the calendar and the urgency of special legislation, the bill may not reach final consideration before adjournment; but in any event the progress thus far has been educational, and the foundation for future efforts in this direction has been laid. The matter is one of importance, and it becomes the duty of each of us to make it a personal matter to urge the establishment and enforcement of laws in this or other States requiring the surrender of the treatment of infantile blennorrhœa from incompetent hands.

The effect of the law in Zurich has been better than we can hope for here; but if every physician in Illinois should prepare himself with the simple knowledge and skill required for the management of these cases, and not shrink from doing his duty, and compelling midwives and nurses to do theirs, the result will be a great economic gain to the State, besides the prevention of incalculable misery to numerous members of generations yet unborn.

PRIMARY SARCOMA OF THE TONSIL.[1]

TWO CASES OF EXTERNAL PHARYNGOTOMY.

BY ROSWELL PARK, A.M., M.D.,

PROFESSOR OF SURGERY, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO.

THE subject of primary sarcoma of the tonsil has already come up before this Association more than once, but is itself of sufficient importance to justify the report of the following two cases upon which operation was performed:

CASE I.—E. L. M——, aged fifty-eight. Duration of present trouble somewhat uncertain. He has had chronic tonsillitis, for which he has been treated by Dr. Stockton for some time: but his complaint of acute pain and soreness, as well as the altered appearance of the parts, only dates back about three weeks. He was sent to me by Dr. Stockton, October 29, 1890, because of a suspicious appearance of the parts in the pharynx. At that time he presented an enlarged, ulcerated, ragged, left tonsil, which gave him severe pain and caused considerable difficulty in breathing and swallowing. A small piece of the ragged border, examined under the microscope, gave appearances which could hardly be explained by round-cell inflammatory infiltration, but which seemed to me distinctly malignant. The base upon which this ulcer was seated was hard, but on the day above mentioned there was no involvement of the palate. Two or three neighboring cervical nodes were enlarged. The family history was good. Four days later the patient was very much worse in every respect. There were more dysphagia and dyspnœa; the neighboring lymph nodes were apparently all involved, and his pain was excessive. Operation was then fully discussed with the patient and his physician, and accepted. November 4th it was performed at the Buffalo General Hospital. Inasmuch as the lymphatics were known to be extensively involved, and because of evident extension of infiltration and ulceration on to the soft palate and the pillars of the fauces, I decided upon external pharyngotomy. A long incision was made from the ear down to the level of the hyoid bone, along the anterior border of the sterno-mastoid. I soon came upon a packet of enlarged lymph nodes, altogether as large as a peach-stone. These were adherent to the carotid sheath. Before removing them entirely I made a second incision at right angle to the first, completely through the cheek and nearly up to the angle of the mouth. This extended down to the bone of the jaw in the neighborhood of the angle, where it was divided with a chain-saw. I then made a tracheotomy, putting in a large tube at the level of the thyroid isthmus, which was divided. I next completed the extirpation of the lymph node above referred to, and then worked down to the tonsil, which was reached without much difficulty.

[1] Read before the American Surgical Association, June 1, 1893.

After isolating it, I opened the pharynx and excised the tonsil, going well down below it, and removing with it as much of the soft palate and uvula as appeared affected. To secure access to the tonsil I had, of course, to divide the digastric, the facial artery and veins, which were tied close to their origin, the palato-glossus, the palato pharyngeus, and part of the pterygoids, the masseter, but not the hypoglossal nerve. I mention the latter particularly because Mikulicz, whose method I in the main followed, has mentioned division of this nerve as a part of the operation. I did not resect the upper portion of the divided jaw, but before completing the operation drilled and wired the two portions together again. The divided pharyngeal mucous membrane was cauterized with a Paquelin cautery. The pharyngeal wound was completely closed with silk sutures, likewise the external wound. A small opening was left for drainage. The operation lasted over an hour and a half; the shock was not serious.

Two days later the trachea tube was removed. Five days later the patient had suffered no particular disturbance, but was rather apathetic. Even from the first he could swallow water and milk, but after a few days there was a leakage of fluids through the external wound. He was fed largely by the rectum.

The patient completely recovered after a somewhat tedious convalescence, and is to-day, two years and a half later, completely well, save that a small sinus upon the cheek, at the site of the original incision, occasionally discharges a little pus, due, probably, to the presence of the silver sutures, which are presumably causing a little irritation, but which he declines to have removed. Motion of the jaw is almost perfect.

A microscopical examination of the parts removed showed the tumor to be a round-cell sarcoma with considerable inflammation, infiltration, and such an unusual number of blood-vessels as to almost entitle it to the designation of angio-sarcoma.

Case II. *Primary sarcoma of the tonsil and pharynx.*—Richard B——, aged thirty-one. Family history unimportant. Always healthy until four or five months ago, when he began to have slight sore-throat and hoarseness. Since then he has lost greatly in weight. He is an unintelligent working-man, who seems to have given but little thought to his condition. Three weeks previous to my seeing him he first noticed a tumor of the right tonsil, which has steadily increased in size up to date. Now —April 30, 1891—he has severe pain in deglutition. He can only swallow liquids, and complains of severe pain along that side of his neck, and speaks very hoarsely. There is a growth projecting from the right side into the oro-pharynx as large as a small orange, 7 or 8 ctm. in diameter, which pushes the uvula off to the opposite side and descends about an inch into the pharynx, rises in the naso-pharynx higher than can be seen, and almost completely stops up the oro-pharyngeal aperture. The cervical lymphatics on each side are enlarged. The growth is moderately firm, but not movable. His condition is desperate, not to say distressing, and he and his family willingly accept an operation, the probably unfavorable outcome of which is fully explained to them.

May 6, 1891, operation at the Buffalo General Hospital, in clinic, chloroform being the anæsthetic; patient having been carefully prepared for the same. The steps of the operation were quite similar to those of the previous case, a long incision being made from the ear to the level of the cricoid cartilage along the anterior border of the mastoid. The lower part of this incision was utilized for the ligation of the common carotid. Then tracheotomy below the isthmus of the thyroid was made. Then, deepening the upper part of the first incision and dividing the cheek, as in the other case, the jaw was divided just in front of the angle. Next attack was made upon the tumor proper, taking pains, as before, not to divide the hypoglossal nerve. The tumor itself was taken out with great difficulty, and was found to extend upward into regions about the base of the skull where it could not be followed. As it was, I removed nearly all of the soft palate on that side in the effort to extirpate it. There was no serious hemorrhage except from a trifling injury to the wall of the internal jugular, which I finally had to tie. The jaw was reunited with silver wire, and the balance of the wound was closed except at its lower part for drainage.

The patient rallied well from the operation, but died on the fourth day, of exhaustion. So much of the wound as was closed by suture had all united *per primam*. A microscopical examination of the growth showed it to be a small, round-cell sarcoma. I feel sure that the outcome of this operation would have been quite different had the patient been operated on three or four weeks earlier.

These are the only cases of primary cancer of the tonsil upon which I have operated. At least two other cases have come under my observation—one six or seven years ago; the other during the past winter, in which the disease had advanced too far. This last was a man, aged fifty-one, seen in November, 1892, whose throat trouble, according to his own account, dated back about six months. From his own statements and those of his physician I am quite positive that the original ulceration began upon the tonsil. When I saw him the tumor was as large as a small billiard-ball, and almost completely occluded the pharynx. Its inner surface was ragged and ulcerated. There was an external tumor as well, which the patient had been foolishly poulticing, and which had been, and was, discharging thin pyoid material. His general health was rapidly deteriorating, and he did not live long.

Altogether, then, I have seen four cases of primary cancer of the tonsil within about six years, and report them in this group because of the rarity of the condition, if one may judge from the literature of the subject.

THE MANAGEMENT OF FOREIGN BODIES IN THE AIR-PASSAGES.[1]

By MAX THORNER, A.M., M.D.,

CINCINNATI, O.

PROFESSOR OF CLINICAL LARYNGOLOGY AND OTOLOGY, CINCINNATI COLLEGE OF MEDICINE AND SURGERY, ETC.

In considering the question as to the management of foreign bodies in the air-passages, I think I may safely omit lengthy excursions into the literature of the subject. It is certainly interesting, from a historical stand-point, to study what the ancients, beginning with Hippocrates, the *divus pater medicinæ*, had to say on this subject; or what reference we might find in the writings of the mediæval authors, or in the literature of more modern times. But for practical reasons, and especially from a feeling of due consideration for the rights of other essayists, it is probably best to simply consider the question from our present knowledge of the subject; that is, to investigate what the experience of to-day, with the present methods of examination and operative procedures, teaches us to be the most rational plan of dealing with foreign bodies in the air-passages. For this reason, therefore, I shall also not enter into an enumeration of all the extraneous substances that have found their way into the air-passages, further than to say that anything from a shoe button to a five-dollar gold-piece may be found in the respiratory tract; and I shall, for like reasons, omit reference to the various exigencies that permitted these foreign bodies to lodge in the air-passages. Let us simply suppose that we have to deal with the fact that a foreign body is somewhere lodged in the air passages.

It is obvious that such a foreign body ought to be removed as soon as possible. The presence of a foreign body anywhere in the respiratory tract constitutes a danger, immediate or remote, to the life of the patient. This danger, certainly, varies in degree according to the location, size, or nature of the foreign body. While it is very slight and generally remote in cases where the foreign body is in the nose, the post-nasal space, or the pharynx,

[1] Read before the Ohio State Medical Society, June 29, 1893.

it increases rapidly in gravity whenever the foreign body has invaded the deeper parts and commences to embarrass the respiratory function, either directly by obstructing the air-passages, or indirectly by pressing upon the soft posterior wall of the windpipe from within the œsophagus. We must, therefore, look upon the presence of a foreign body in the deeper air passages as a constant menace to the life of the patient, notwithstanding the well-recorded fact that occasionally foreign bodies were lodged for a long time in the air-passages, yet did not create any serious disturbance; or where they were expelled, after a shorter or longer term, by nature's own efforts. Such cases are simply exceptions. The number of cases is much larger where the most serious results followed the entrance into the air-passages of extraneous substances, when the expectant method prevailed. I shall not tire you with statistics made up by various compilators, regarding the question of interference or non-interference in such cases. But I may state that ample experience has shown the mortality to be much greater (in fact again as great) in cases where the foreign body was not removed, than in the cases where operations were undertaken for the relief of the patient. *Laisser aller* is a dangerous maxim in these cases; many a life might have been saved by a timely operation.

I shall briefly relate two cases from a larger number of my own, of which the first apparently contradicts these statements, while the second confirms them.

Case I.—Mr. W. D——, aged thirty-five, was quietly standing at his window one Saturday afternoon in May, 1890, when he felt something work up in his throat. Before it could be ejected it slipped down again; he immediately experienced a feeling of suffocation and the breathing became difficult. Dr. N. P. Dandridge, who was consulted, failed to discover anything wrong with the young man. The patient had eaten green peas with his dinner, and expressed himself as confident that a pea had slipped down the trachea. The breathing became easier for a while; but when the troublesome sensation could not be relieved, Dr. Dandridge and Dr. William Carson examined the patient again, making a very thorough physical examination, without being able to locate the foreign body. Although the patient was at intervals entirely free of any annoying sensation, he still insisted that the pea was somewhere in his chest. Later on in the afternoon the patient had severe paroxysms of coughing, when Dr. C. R. Holmes was consulted, who referred the patient to me. The patient was one of those individuals in whom it is easy to inspect, with the laryngoscope, the larger part of the trachea. But neither this nor repeated physical examinations could produce a positive proof as to the presence or whereabouts of the foreign body. In fact, there seemed to be a general doubt among the physicians as to his actually having a foreign body in his air-passages. In the evening the patient was taken to the gymnasium, and hung head downward, and pounded on the back and chest, in the hope of removing the body by gravitation, but without avail. That night and Sunday were passed in great distress, the frequent paroxysms of coughing were very violent. Monday gave no relief, and Tuesday morning he felt very exhausted. The chest was so painful that he endeavored to suppress the cough as much as possible. Tuesday morning, sixty six hours after the beginning of the trouble, he suddenly had a severe coughing paroxysm, during which he coughed up a large sized green pea. In a few days all the above mentioned symptoms disappeared, and he has never experienced any ill effects since.

Case II.—Miss E. R——, sixteen years of age, while eating soup about two months ago, had a severe choking spell, and declared that she had swallowed a bone. She soon became dyspnœic, and physicians were sent for. When Drs. Schoemer, Schwagmeyer and Topmöller arrived they found the girl unconscious; there was marked dyspnœa and pronounced cyanosis. Failing to discover a foreign body in the pharynx or in the upper larynx they summoned me in consultation. Upon arrival, about one hour after the accident, I found the patient lying on a sofa, unconscious, and somewhat cyanotic. She was breathing with great difficulty, the loud inspiratory noise being audible all over the room. The pulse was small, indistinct, and very rapid. During inspiration the jugular and epigastric regions were deeply retracted.

A laryngoscopic examination could be made with the greatest difficulty only, on account of the comatose condition of the patient. However, I was enabled to determine that there was no foreign body in the larynx, but thought to have twice seen a whitish substance below the vocal cords, without, however, being absolutely sure of it. It may be added that the father of the girl, a very sensible man, had some doubts about his daughter actually having a foreign body in her throat, since she had had choking spells of a hysterical order before, though of a less severity.

After a brief consultation immediate tracheotomy was decided upon, as the patient was rapidly sinking. Accordingly the high tracheotomy was done. I selected this instead of the low operation, because the surgeon is able to do it in much less time, which is of importance when death from suffocation is impending; and secondly, because an opening in the upper tracheal rings is more adapted to the removal of a foreign body lodged in the subglottic space than the opening afforded by the lower tracheotomy. No attempt was made at the time of the operation to find the foreign body, as the patient was almost apnœic. But within a few days I began the search for the foreign body, and discovered it impacted in the space above the wound channel. In the presence of the physicians who had seen the case with me, I removed, with a small pair of curved forceps, a quadrangular piece of bone, of about the size of a five-cent piece, through the tracheal opening, from the subglottic space, where it had been held firmly impacted by its rough edges. The patient, after the removal of the foreign body, made a quick and uninterrupted recovery.

If we analyze these two cases we may arrive at the conclusion that, in the first case, tracheotomy would not have been called for, for two reasons: Firstly, because there was some doubt regarding the pea having actually entered the air-passages; secondly, because the patient recovered spontaneously; while in the second case the threatening symptoms demanded, and the recovery of the foreign body justified, the operation. Now, after a number of years have passed since the first case made the spontaneous recovery, I must confess that I am at present of the opinion that I ought to have recommended tracheotomy in the first case also. That the foreign body would be spontaneously expelled is a fact that could not be anticipated; it is certainly the exception, and our therapeutical measures ought not to be guided by exceptions. The proportion of cases where patients under similar conditions perish without operation, is much larger than where an operation is performed. Some authors place this proportion of mortality as about two to one. I recollect a case, from the practice of a colleague, which illustrates this point, and which I may be permitted to briefly mention, as it never has been published. A vigorous young man was unfortunate enough to draw into his windpipe a dried white bean, which he held playfully in his mouth. After a severe coughing paroxysm the patient had a sensation of pressure below the sternum. A physician was consulted, who, after a thorough examination, proposed tracheotomy. This was refused, even when after periods of temporary relief excessive cough and difficult breathing returned at short intervals. The patient died about four months after the accident, of pneumonia. It is reasonable to suppose that by an early tracheotomy the foreign body might have been removed, or its expulsion facilitated. And while I am far from asserting that all cases in which tracheotomy is done will get well, I still believe that the chances are a great deal better for the patient if the operation is performed. There was also some doubt in my second case as to the presence of a foreign body; but the history of the case, as well as the threatening symptoms, demanded an immediate opera-

tion, and the possible failure of finding the foreign body after the operation could not greatly have militated against the necessity of the operation.

If we, therefore, concede that foreign bodies ought to be removed from the air-passages in all cases, we may briefly examine the different methods.

We may safely omit from discussion such obsolete methods as causing the patient to sneeze or to vomit, or that of succussion of the chest and back of the patient while he is put in a position with his head hanging downward. Although they may have occasionally aided the expulsion of the foreign body, they are generally futile, and at times even dangerous, inasmuch as often valuable time is lost with such procedures.

The last-named measure is also liable to cause spasm of the glottis if the foreign body should happen to strike the lower surface of the vocal cords, or may lead to impaction of the foreign body in the subglottic region.

There remain, then, operative measures only, which are either endo laryngeal, *i.e.*, the removal of foreign bodies by instruments introduced through the mouth, or extra-laryngeal, *i.e.*, the opening of the air-passages for the purpose of relieving dyspnœa and of removing the foreign body.

It stands to reason that we should always try to remove the foreign body from the pharynx and from the larynx by the endo-laryngeal method; that, on the other hand, the extra-laryngeal method is indicated in such cases where foreign bodies have entered the trachea or bronchi; or whenever the life of the patient is in immediate danger of suffocation, when there is no time or no possibility of making attempts at endo laryngeal operations. This last indication permits, of course, of a certain latitude, as being greatly dependent upon the circumstances of the case and the dexterity of the physician. That tracheotomy ought also to be performed in cases where the foreign body has entered the bronchial tubes, is advised, not so much with a view of extracting the foreign body from the bronchus, as for the purpose of directly exciting paroxysms of cough, and thus to facilitate the expulsion of the foreign body through the artificial opening.

The foregoing remarks refer mainly to such cases where there is no doubt that a foreign body has actually entered the air-passages. I am, however, also of the opinion that in doubtful cases, where there is no absolute proof of the presence of a foreign body in the air passages, yet where there is good and sufficient reason to believe, by circumstantial evidence as it were, that an extraneous substance is lodged somewhere in the air-passages, that in such cases we should give the patient the benefit of the doubt. And while I am far from speaking lightly of the operation of tracheotomy, I cannot help thinking that in many cases of doubt it will help to save life.

141 Garfield Place.

Disinfection (?) of Baggage on the Russo-German Frontier.—The process as witnessed at Eydtkuhnen (*The Lancet*) was carried out by women. The top and sides of each package were wiped over with a damp flannel that had been dipped into some hot fluid. The fluid was black with dirt. With the same flannel the upper surface of each article contained in the boxes was washed over, irrespectively of its nature, woollen clothes, boots, and white shirts receiving the same dirty smear. The inner surfaces of folded articles were not touched. Linen that had been worn was detained for disinfection by steam.

Total Abstinence in the Indian Army.—The membership of the Indian Army Temperance Association has reached its highest point. The whole strength of the British forces in India is about 68,000, and as there are 20,111 men who are abstainers, the progress of sobriety has been remarkable. At Singapore, 130 artillerymen out of a total strength of 200 are abstainers.

THE VALUE OF EARLY URETHRAL INJECTIONS IN THE TREATMENT OF ACUTE GONORRHŒA.

By JAMES PORTER FISKE, M.D.,

NEW YORK.

As a rule, early urethral injections in gonorrhœa are looked upon with disfavor, and regarded as meddlesome treatment.

Many physicians, at the present day, regard early urethral injections as an invitation to the gonococci to invade the neck of the bladder. What I wish to mention here is the feasibility of clearing out the anterior urethral canal, in acute gonorrhœa, by injecting a mild cleansing solution, and at the same time not endangering the deep urethra.

If we can keep the urethral canal fairly clean and prevent the discharge from accumulating, not only in the canal at large, but in the various sinuses and pockets leading thereto, we are gaining a very important point in our treatment of the inflammation, and we are conducting it on sound surgical principles, viz., irrigation and drainage.

We have all seen cases where the penis is hot and swollen, and the urethra giving vent to a purulent discharge, irritating and very profuse; so profuse that the urethral canal is seemingly almost ready to burst. The urethra is really a great sinus, the walls of which are acutely inflamed, and giving out these large amounts of pus. Such a condition, in any other part of the body, would lead the surgeon to lay open the sinus, irrigate, and obtain free drainage. This we cannot do. But we can clear away temporarily the inflammatory products, and so give free drainage to the tract for the time being.

How is this to be accomplished? Simply by urethral injections. We must use a fluid absolutely non-irritating, and yet preferably an antiseptic. A one-half per cent. salt solution, at a temperature of 30° to 32° C., is the ideal fluid.

The method employed determines whether this procedure will be a success or a disastrous failure. Use a blunt-nozzled urethral syringe, and absolutely no force in emptying it, and most gratifying results will be obtained.

In employing this method the operator must remember never to inject one drop of the solution beyond the point where the patient experiences the slightest sense of fulness in the perineum, or there is reason to believe the fluid has found its way up to the compressor urethræ. At this point release the fluid and repeat the procedure, and so thoroughly flush out the anterior canal. In irrigation by this method it is necessary to repeat once, *i.e.*, use two syringefuls at each sitting.

What is effected by this method of treatment? Instead of the urethral canal being clogged up with a mass of inflammatory products, we obtain a canal comparatively free from discharge for the time being; and from my results I am satisfied, if this procedure be properly done, we decidedly lessen the chances of a deep urethritis, or accompanying epididymitis.

This urethral flushing will have to be repeated every two to four hours at first, and later less frequently, as the discharge decreases in amount.

As a result, we actually lessen the severity of the symptoms of the acute stage, and may shorten the duration of this stage. I have noticed that two prominent symptoms are invariably relieved, viz., pain on urination and that feeling of general uncomfortableness in the region of the perineum and urethra.

We distinctly lessen the chances of gonorrhœal bubo, by preventing the accumulation of pus; and in addition, it gives to a patient a sense of cleanliness attained by no other method.

Of the radical cure of acute gonorrhœa, two methods have been placed before the profession. One, the method of injecting strong silver nitrate solution (grs. lx. to

℥ j.) into the urethra; the other, that of continuous irrigation.

The use of the first, at the present day, would be considered little less than malpractice; and of the second, we must notice that while it is being carried out it entails the necessity of a foreign body, usually a catheter with openings directed backward, lying in the urethral canal, and irritating the sensitive mucous membrane by its presence. This latter method, that of continuous irrigation, has a very limited use, necessitating as it does the patient taking to his bed.

While the measure I am advocating is in no sense a radical cure, still I am convinced it accomplishes much that is claimed for the more severe procedure (continuous irrigation) by its most enthusiastic advocates.

I have selected two cases which I shall report, in which I carried out this method of urethral injections; the results, though showing nothing phenomenal, still were highly satisfactory both to my patients and myself. I should state that I have never had a case of gonorrhœal bubo or deep urethritis follow this procedure. It does not materially shorten the duration, in the great majority of cases; but it does alleviate symptoms, a very important point, and it does, when properly carried out, lessen the chances of complications.

Case I.—W. B——, aged forty. Never had a private disease before. First seen second day after discharge commenced. Had connection on two different occasions; first, six days previous, and second, four days previous, to appearance of discharge.

Glans penis red. Painful irritation, and painful erections. Discharge rapidly became thick, creamy, purulent, and very profuse. Patient was a married man, and also suffered from severe mental depression. Patient was put on alkalies. Alcohol stopped, diet regulated, suspensory bandage ordered as a precaution, and patient instructed to keep quiet. I put him on a salt solution one half per cent., to use as a urethral injection, every two hours at first.

Result.—Discharge was thinner, less profuse, pain on urination almost absent, and patient was so much relieved at improvement that his mental condition was greatly benefited.

As discharge became thinner and less, the injections were used less frequently. At end of seven days from time I saw him injections were reduced to three a day. In the meantime I had put the patient on ol. santali, and he left me cured in twenty-one days from onset.

Case II.—W——. Patient has had gonorrhœa a number of times, and during past year has had at times a gleety discharge.

Five days after coition he noticed discharge from urethra, and within forty-eight hours discharge was profuse, thick, and creamy. Great pain on urination. He commenced to take Lafayette mixture ℥ ij. t.i.d., as he had heard of it.

Three days later he consulted me. There had been no abatement of the symptoms. The inguinal glands on both sides were swollen, tender, and caused him constant pain; in short, he was threatened with gonorrhœal bubo. His stomach had been upset by the Lafayette mixture and alcohol, and he was in great mental distress.

Both Lafayette and alcohol stopped. Patient put on alkalies, and diet regulated. Put on urethral injections every three hours of one-half per cent. salt solution. Discharge became thinner and less profuse. Pain and irritation of the parts markedly reduced, and his mental condition at once improved. Injections were kept up as required, every few hours, and ol. santali given internally. The acute stage was shortened, but the after-treatment was tedious, as he had an old stricture.

So far we have not discussed the direct application of drugs to the urethral mucous membrane in acute gonorrhœa. We have only cleansed the canal, and many surgeons will stop here, satisfied with this very important achievement.

Of course, it would be absurd to apply medication by means of the first injection, as the discharges would prevent the drug coming in direct contact with the mucous membrane. We might just as well attempt to apply remedies to an ulcer on the leg before removing the bandages.

After carrying out the procedure heretofore described we may make use of a medicated injection, such as H_2O_2, in varying strengths, zinc sulpho-carbolate, etc.

These injections I use only in carefully selected cases. If the urethra appears particularly sensitive, or I have doubts as to its tolerance of direct medication, then I rest satisfied with the saline injections alone.

As a rule, during the acute stage of gonorrhœa I should advise the general practitioner to use only the saline solution, leaving the medicated injections in the hands of the specialist.

RECTAL STRICTURE OF PUERPERAL ORIGIN RELIEVED BY LAPAROTOMY.[1]

By N. STONE SCOTT, M.D.,

CLEVELAND, O.

CONSULTING SURGEON TO THE CITY HOSPITAL; VISITING PHYSICIAN TO CHARITY HOSPITAL; LECTURER ON OSTEOLOGY AND GENITO-URINARY DISEASES, UNIVERSITY OF WOOSTER.

It is with considerable trepidation that I offer to this society, the *élite* of the medical profession of this great State of Ohio, in the words of Joseph Cook, "before whom I ought to stand dumb," a new classification of rectal stricture. The case I have to report to-day has been of especial interest to me, and, on looking up the literature, appears to be unique. The consideration of the subject forces me to divide rectal stricture into true and false.

In a true stricture the pathological narrowing is situated in one or more of the structures of the rectum.

By a false stricture of the rectum will be understood a stricture wherein the pathological condition is situated in the peri-rectal tissues, and not in the structures of the rectum. This must not be confounded with obstruction of the rectum caused by a tumor or misplaced organ.

With true stricture and with obstruction of the rectum this paper does not deal; but it is my wish to show that false stricture not only exists, but may be better treated than by the methods recommended in the text-books. The case giving rise to this research is as follows.

Synopsis.—Symptoms of rectal stricture following confinement. Laparotomy. Recovery, with a complete cure of the stricture.

History.—Mrs. M——, aged thirty-six, a large, well-built woman, has always enjoyed good health until her last confinement. She first menstruated at seventeen years; her periods have been regular in time and quantity, and accomplished without difficulty. She has given birth to four children; one ten years since, one six, the third three years ago, and one in April, 1892. All the labors were easy and convalescence normal except the last. The first child died at the age of seventeen months, of diphtheria; the last one lived but twelve days; the other two are healthy. No trace of syphilis or gonorrhœa in husband or wife. On the second day after confinement she complained of severe pain in the lower part of the abdomen, and on the eighth day a rectal tenesmus supervened, there being frequent passages of mucus streaked with blood. This continued some two months; gradually the acute pain and bloody discharge subsided, but she did not regain her former good health.

Her doctor told her that she had "grippe of the bowels." No vaginal examination was made. In July she consulted one of our leading gynecologists, who put her to bed, gave her hot douches, and said to her, "You will have to stay in bed until the snow flies." For two and a half months she had no symptoms directly referable to the rectum, but after the latter part of August

[1] Read at the meeting of the Ohio State Medical Society, June 28, 1893.

the difficulty she experienced in getting her bowels to move gradually increased in severity.
